SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.—At a meeting held on February 18th, Dr. A. FORBES, Vice-President, in the chair, Dr. RALPH P. WILLIAMS, School Medical Officer of the city, read a paper on *Medical inspection of school children in Sheffield*. After describing the objects and history of medical inspection, the necessity for some organization of this kind was pointed out, resulting from (a) the inquiries of the various Royal Commissions which had recommended it, (b) the large amount of physical defects found in school children by the earlier investigators, and (c) the revelations in connexion with recruiting for the Boer war. The work done in Sheffield before the passing of the Education (Administrative Provisions) Act of 1907 was next described. The children then attending the schools were inspected (66,590 in number). Of these 5,475 were examined, and 4,741 letters were sent to parents suggesting that treatment should be obtained from the family doctor. Second letters were sent to those parents who had disregarded the first. As a result of the letters sent about 45 per cent. of the children obtained treatment. The conditions found included 2,066 cases of defective vision, 385 sore eyes and lids, 1,141 adenoids and enlarged tonsils, 130 discharging ears, and 151 rickets. The schedule being used under the new Act was discussed, it being found by experience that about forty children per day could be examined by a whole-time medical officer. The question of verminous children was fully dealt with. Three whole-time school nurses had been appointed, and their work was supplemented by the large staff of women sanitary inspectors. In cases where no improvement took place after two visits from the nurse the home was visited by the school medical officer and the parents warned, or if the state of the home was very bad the children were "removed to a place of safety" on a warrant obtained from the magistrate (Section 10, Prevention of Cruelty to Children Act, 1904). Five families of children had been so removed since last July, the parents being prosecuted for neglect, sentences varying from six months' to one month's imprisonment having been passed. The arrangements for treatment were mentioned. The Education Committee subscribe to the hospitals, and by this means "recommendations" were provided for children (after full investigation as to the parents' means). Mr. MILES H. PHILLIPS read the notes of a case of *Dystocia due to excessive development of the child*. The head was born unassisted, in the unreduced right occipito-posterior position. Delivery of the trunk was only effected after amputation of the head and both arms, evisceration, and the application of the cephalotribe to the spine. The child weighed 16½ lb. The excessive bulk was chiefly due to a deposit of dense subcutaneous fat, which was 1½ in. thick over the loins. Pregnancy had been prolonged three weeks over the calculated time. The child was living when the head was born. The mother, fortunately, had a large pelvis, and her previous children had been born naturally. Dr. ARTHUR HALL showed two cases of *Bronchiectasis*. One followed tooth extraction, the acute symptoms of septic bronchitis subsiding after a tooth stump had been vomited. The second was an old case of phthisis where the physical signs had remained the same for at least seven years. The cardiac impulse was in the axilla. In addition to the signs of cavity at the left base, there were crepitations synchronous with the heart-beat. He also showed a case of *Herpes zoster* of the second division of the fifth nerve.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—At a meeting held on February 19th, Dr. W. H. CHEETHAM, who was in the chair, read a paper on the *Medical inspection of school children*. Dr. E. F. TREVELYAN read a paper on *Birth palsy*, especially in reference to the distribution of the paralysis and prognosis. Mr. H. LITTLEWOOD

showed a *Columnar-celled carcinoma* growing from the anterior surface of the sacrum and invading that bone. The tumour was felt by rectal examination as a smooth elastic mass the size of an egg, and was entirely unconnected with the bowel. No other growth was recognized in the ovary and elsewhere, and the tumour was regarded as originating from the post anal gut. The patient was a woman, aged 63, who had suffered from agonizing sacral and coccygeal pain for several months, dating back to an injury—a fall upon the lower part of the back. Mr. W. THOMPSON showed (1) a specimen of *Subacute necrotic pancreatitis* from a woman aged 44. When seen there had been five months' history of abdominal pain and vomiting, and a transverse tumour could be felt in the lower epigastric region. At an exploratory operation the tumour was found to be pancreatic, fat necrosis was observed, and the gall bladder, which contained stones, was drained. There was considerable pyrexia. The patient died twenty-three days after the operation. At the post-mortem examination there was destruction of the head and part of the body of the pancreas, with suppuration burrowing into the root of the mesentery. The left half of the pancreas was apparently normal. (2) A patient, a man aged 46, from whom about three-quarters of the stomach had been removed. He was extremely emaciated, but was now improving, eating chicken, etc., fourteen days after operation. There was extensive malignant growth of the pylorus extending along both curvatures. There was massive enlargement of the subpyloric glands, those along the coronary arteries being also involved. (3) A *Recurrent myeloid sarcoma* from the region of the coccyx, the growth being the size of a small cocoon. The coccyx had been removed two years before; signs of recurrence were noted six months ago. Dr. E. F. TREVELYAN showed a man, aged 52, with a slight *Residual paralysis* in the left hand as a consequence of a total brachial plexus paralysis due to a dislocation of the left shoulder. As there had been no improvement for nearly a year, this paralysis was looked upon as permanent. Mr. A. S. GRÜNBAUM showed specimens of extensive *Idiopathic and traumatic pontine hæmorrhage*—one, from a man aged 65, setting in spontaneously during work, the other, from a man aged 71, the result of being knocked down by a tramcar. Dr. MAXWELL TELLING and Mr. J. F. DOBSON showed an infant, 12 months old, in whom a large *Pancreatic cyst*, noticed since the age of 9 months, had been drained successfully. Cases and specimens were also shown by Mr. JOHN W. HYSLOP, Mr. A. L. WHITEHEAD, and Mr. MICHAEL TEALE.

LIVERPOOL MEDICAL INSTITUTION.—At a meeting held on February 11th, Mr. T. H. BICKERTON, President, in the chair, Dr. W. B. WARRINGTON described a case of *Myasthenia gravis* in a woman aged 32 years. The ptosis often so readily seen was not marked, though it could be produced to some extent by fatigue. There was extreme weakness of the masseters, which gave the characteristic myasthenic electric reactions. In other ways the case was quite typical. Dr. GLYNN referred to a case which commenced with giddiness, double vision, and ptosis, the latter being transitory. There was considerable loss of voluntary muscular power of the legs after exercise or excitement, and death occurred in twelve months from bulbar symptoms, these developing and proving fatal in four days. Drs. MURRAY BLIGH and ERNEST GLYNN read a note on the *Diagnosis of typhoid fever* by bacteriological examination. Their method was based on lines suggested by Coleman and Buxton, of New York, particularly in the employment of sterilized ox bile medium. In 8 out of 15 cases of typhoid examined in the second and third week they obtained positive results. The method proved of distinct value in 2 cases in which the nature of the disease was obscure. Mr. MONSARRAT read a paper on *Cancer of the breast*. He discussed the difficulties of early diagnosis. He described the extent of the operation undertaken in 37 cases and their after-histories. There was no recurrence in 20 cases during a period extending from five years to one year. Recurrence had taken place in 14 cases during periods ranging from four years to within one year. Mr. PAUL referred to the importance of removing breasts affected with intractable involution mastitis before they became malignant, and the great value of rapid sections. He thought the modern operation gave decidedly improved results. Mortality from

the operation was very low. He had removed the breast over 200 times during the last five years without a death, and had no death since 1901. In thirty years he had had only four deaths from breast operations—two from sepsis and two from acute mania.

GLASGOW SOUTHERN MEDICAL SOCIETY.—At a meeting on March 4th, Dr. COWAN delivered an address on arterio-sclerosis, first describing the pathological changes which occur in the vessels and constitute this condition. With reference to the kidneys, he pointed out that arterio-sclerosis was most common where on post-mortem examination the small red kidney was found. It was also common with the small white kidney, but infrequent with the large. Renal disease might, however, be secondary to arterio-sclerosis. Another secondary condition of serious import was fibrosis of the heart muscle, which followed upon sclerosis of the coronary arteries. Emphysema of the lungs also occurred readily when the vessels were sclerosed. With regard to etiology, arterio-sclerosis resulted from long-continued high pressure in the blood vessels; in this disease all the vessels were affected and it thus differed from atheroma. Referring to the Riva-Rocci sphygmomanometer, he considered a single observation of the blood pressure of no value. A continuous chart of the patient's blood pressure was of value, but from this record alone the patient's general condition could not be estimated. For example, with a deterioration in the patient's general condition, the blood pressure might either be rising or falling. The symptoms resulting from arterio-sclerosis might be classed as either pulmonary, cardiac, renal, or cerebral. From pulmonary disease resulted dyspnoea, orthopnoea, or irregular breathing, and from cardiac insufficiency, oedema or dropsy. Headache, often associated with vomiting, was caused by renal inadequacy. *Petit mal* was one of various cerebral symptoms which might ensue. From arterio-sclerosis also continuous cardiac pain or attacks of angina pectoris might result. The aim of treatment should be to eliminate poison from the blood and prevent stress.

NORTHUMBRELAND AND DURHAM MEDICAL SOCIETY.—A meeting of this society was held at the Royal Victoria Infirmary, Newcastle-upon-Tyne, on February 11th. The first portion of the evening was devoted to an exhibition of medical and surgical cases, followed by two short papers by Mr. A. S. PERCIVAL and Mr. R. J. WILLAN. Mr. Percival's subject was a *Pathological suggestion, based on electrical analogy*: that of Mr. Willan was some *Practitioner's experiences with the urethroscopie, cystoscope, and catheterization cystoscope*. The following were among the cases shown:—Dr. DRUMMOND: Two cases of *Musculo-spinal paralysis*; three cases of *Hemiplegia and Myasthenia gravis*. Sir THOMAS OLIVER: *Innominate aneurysm*; *Lymphadenoma*; *Fibroid phthisis*; and *Aortic incompetence*. Dr. BEATTIE: *Locomotor ataxia*, with anterior tibial peripheral neuritis; *Syphilitic aortitis*, with fusiform dilatation of the arch and aortic regurgitation; *Splenomedullary leukaemia treated by exposure to x rays*; *Acute transverse myelitis in a boy 14 years of age*; *Hydrocephalus*; and *Catarrhal jaundice due to infective cholelithiasis*. Dr. W. E. HOME: *Splenomedullary leukaemia treated with x rays*; *Hodgkin's disease*; *Pseudo-hypertrophic muscular paralysis*; *General paralysis of the insane*; *Perniciou anemia*, showing great improvement by open-air treatment; *Syphilitic spinal meningitis in a man aged 56*, the infection being acquired six years ago. Dr. HORSLEY DRUMMOND: *Cases of Heart disease*. Dr. PARKIN: *Disseminated sclerosis*; *Mitral stenosis*; *Winged scapula*; *Charcot's hip-joint*; and *Fibroid phthisis*. Dr. BOLAM: *Pityriasis rosea*; *Scleroderma*; *Hydroa estivale*; *Favus* (two cases), and *Tinea barbae*. Mr. RUTHERFORD MORISON: An old man with a *Gluteal aneurysm* which was being cured by injections of tinctura ferri perchlori into the sac; and a case after the repair of a *Ruptured duodenal ulcer* followed by a gastro-enterostomy. Mr. JOHN CLAY: An elderly female with an *Obscure pulsating tumour at the root of the neck*, which was probably an *aneurysm of the first part of the subclavian artery*. Mr. W. G. RICHARDSON: A young female from whom he had removed a false palate and tooth from the gullet by *Oesophagotomy*. Mr. J. V. W. RUTHERFORD: Two cases where large areas had been successfully skin-

grafted by the Method of Thiersch. Mr. A. M. MARTIN: An *Epithelioma of the heel*; *Sarcoma of the leg*; and a huge *Intramascular lipoma of the thigh*. Mr. CLAY: Dislocation at the hip-joint reduced five weeks after injury; the patient was allowed to get up on the third day, and was now in full work.

NORTH OF ENGLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.—At a meeting held at Liverpool on February 19th, Dr. J. W. MARTIN (Sheffield), the President, in the chair, Dr. J. J. O'HAGAN (Liverpool) showed a *Fibromyomatous uterus*, with bilateral ovarian dermoid cysts, which had been removed by total hysterectomy. Dr. J. E. GEMMELL and Dr. LEITH MURRAY (Liverpool) showed (1) *Myofibroma of the vagina*; (2) *Sarcoma of the great omentum*, which had presented a soft, solid, freely movable tumour in the left hypochondrium. It could be pushed into the pelvis and had simulated a dislocated spleen. It was easily excised. There was no ascites and the other abdominal organs were normal. Dr. D. LLOYD ROBERTS (Manchester) showed a specimen of *Cystic fibromyoma of the uterus*, and read notes of a case of *Cæsarean section*, performed, before the onset of labour, on account of a flattened pelvis (C.V. 3 in.). Craniotomy had been performed on three previous occasions. Involution of the uterus was slow, and on the eighth day symptoms of sepsis appeared. The uterus was explored and a large clot of blood removed. Recovery was then uninterrupted. In closing a discussion, Dr. Lloyd Roberts stated that he always, if necessary, dilated the cervical canal before suturing the uterine incision, that ergot was given during the operation, and that, in his opinion, the retention of blood clot was due to pressure of the lower uterine segment against the promontory. Dr. Lloyd Roberts also showed a *Recurrent tumour of the vagina*, enucleated piecemeal from a woman of 43. Microscopically, it consisted chiefly of fibromyomatous tissue, though one part suggested sarcoma. Dr. J. E. GEMMELL stated that, nine years previously, he had enucleated a vaginal growth the size of a Jaffa orange from the patient. Clinically he had considered it a sarcoma, but microscopically it had been described as a degenerating fibroid. Dr. G. W. FITZGERALD (Manchester) showed the specimen and read notes of a case of *Primary carcinoma of the vagina* occurring in a nullipara aged 26. The ulcerated growth, which occupied the left fornix, was freed from below, and then removed, together with the uterus, by the abdominal route. The patient made a good recovery. Section showed that the growth—an epithelioma—though invading the cervix, was not connected with the mucous membrane of the cervical canal. But it might possibly have arisen from the epithelial covering of the portio. Dr. H. R. CLARKE (Manchester), in a paper on *Cavernous conditions occurring in the uterus*, pointed out that the myometrium of the infantile uterus consists of a network of fibro-muscular tissue enclosing large cavernous spaces, which are lined with endothelium, and filled, in most of his specimens, with blood. During development arteries extend from the fibrous trabeculae into those spaces invading the venous wall, and producing, in the early stages, a condition which the author likened to the corpus cavernosum of the penis. The arteries grew more rapidly than the venous spaces, and so, by this process of condensation, the dense condition of the adult myometrium was reached, and the arteries of the adult uterus came to be surrounded by venous spaces. The author suggested that the angiomatic changes seen occasionally in uterine fibroids might possibly be dependent upon this developmental process. The paper was discussed by Dr. BLAIR BELL, Dr. LLOYD ROBERTS, and Dr. A. W. W. LEA. Dr. CLARKE replied.

ONE of the euphorbias in Queensland, the *Euphorbia pulchifera*, is commonly called the Queensland asthma plant; it has a local reputation for curing that disease, and several pharmaceutical preparations of the plant are sold in Australia. Recent chemical examination has shown that the green plant contains 79 per cent. by weight of water and 3 per cent. of ash, the amount of vegetable matter being therefore estimated at 18 per cent. The dried plant contains an alkaloidal substance, in the proportion of about 1 part in 1,000, and a glucosidal substance in a proportion of not more than 4 parts in 1,000; it is thought possible that one or both of these may have active properties.

Reviews.

DIABETES.

THE lectures which were delivered by Dr. PAVY¹ before the Royal College of Physicians during last November and December contain a lucid presentation of his theory of the physiology of sugar absorption. If we may venture to attempt to do justice to these views in a brief summary, it may be said that Dr. Pavy holds that when sugar circulates with the blood it escapes by the kidney, and that the normal quantity of sugar in the urine corresponds to the normal amount of sugar in the blood. It is true that the normal glycosuria is too slight to be revealed by Fehling's test, but its existence is hardly any longer disputed by competent authorities. When sugar is injected into the blood it appears at once in the urine. Dr. Pavy considers these facts inconsistent with the current doctrine that sugar is poured into the circulation as glucose and travels with the blood to the tissues, where it is normally assimilated. If this were a physiological process he holds that glycosuria would always occur, and he thinks the conclusion inevitable that the sugar must travel in the blood in some combined form. He supposes the molecule of bioplasm to be provided with innumerable arms for junction with suitably constructed foodstuffs, and that in this way it can carry both carbohydrate and protein to the tissues, where they are detached and utilized. He explains phloridzin glycosuria, in which, as is known, there is no hyperglycaemia, by supposing that the renal epithelium has the power of detaching the carbohydrate molecule from its side-chain attachment as the blood passes through the kidney. While admitting that the liver plays an important part as a storehouse of glycogen, he points out that the results of Eck's fistula, in which the portal vein has been successfully anastomosed to the inferior vena cava, where the liver is entirely excluded from the circulation without the occurrence of glycosuria, proves that the liver cannot be the important physiological barrier to prevent glycosuria which current physiological theories assume. He believes it must be admitted that sugar disappears during its passage through the intestinal wall, and we understand him to suggest that the theory outlined above affords an adequate explanation of its disappearance and its carriage to the tissues. But Dr. Pavy also points out that the enormous increase of lymphocytes in the intestinal epithelium and lacteals has never received the attention it deserves. He regards these as freshly proliferated rapidly growing bioplasm, formed in the presence of suitable pabulum, and he believes that it is in them that the foodstuffs travel to the circulation, where the lymphocytes disappear by a process of autolysis, having meanwhile effected by ferment action the conversion of the nitrogenous results of digestion into albumens and globulins. Glycosuria results whenever this process fails, and is in proportion to the extent of the failure. Thus there may be a larger supply of carbohydrate foodstuff than can be transported by the existing means, which may be normal as in experimental glycosuria produced by feeding with excess of glucose, or slightly diminished as tends to be the case as age advances, or decidedly and greatly diminished in the various degrees of diabetes. He thinks that the pancreas may secrete a substance which favours the taking on of the carbohydrate atom, or, to use the language of Ehrlich, the pancreas secretes the ambocceptor, and that in this way the relation of pancreatic disease to glycosuria is to be explained. We should not do justice to Dr. Pavy if we omitted to say that his lectures contain much more than the exposition of this purely theoretical doctrine. He has some exceedingly useful remarks upon the worthlessness of many so-called diabetic foods, and makes a decided point against Professor von Noorden, who has extolled his "oat cure" by comparing the results he obtained from it with those observed when patients were taking the bread made by Rademann of Frankfurt. Some of this maker's diabetic white bread examined by Dr. Pavy in June, 1900, contained 73.4 per cent. of starch, while "Zwieback," examined in March, 1898, contained 72.1 per cent. of starch, and another sample examined in March, 1902, contained 64.8 per cent. of starch. More recent examinations in the early part of last

¹ Lectures on the Pathology and Treatment of Diabetes Mellitus. By F. W. Pavy, M.D., LL.D., F.R.S.

year gave somewhat better results, but these figures show that no scientific conclusions should be drawn from any comparisons based on the assumption that these foods contained little or no starch.

Professor NAUNYN has written for the use of practitioners a small book giving the necessary data for prescribing diabetic diets,² and it would be well if some one would publish its equivalent in English, *mutatis mutandis*, as there are necessary changes to be made in dealing with English patients and with English articles of food. The first table gives the percentage of fat in different foodstuffs, such as meat, fish, butter, bacon, sausages, eggs, and cheese. The second gives the percentage of fat and sugar in milk, cream and milk preparations; and the third gives the carbohydrate percentage of various farinaceous substances, vegetables, and fruits. In the fourth section there is information, not in tabular form, on the sugar contents of alcoholic drinks. Then follows a table on the value, in heat units, of different articles of food; and a specimen diet, containing 2,700 heat units, for a patient weighing 150 lb. (75 kilos). In conclusion, a brief account of the principles upon which diabetic diets should be constructed is given, and a bill of fare arranged for each day of the week, with the quantity and the heat value of every item of the diet.

The fasciculus on diabetic coma in Professor Albu's System of Treatment could not have been entrusted to better hands than those of Dr. A. MAGNUS-LEVY,³ who has done so much good work in this and allied departments of medicine. The text opens with the following quotation from Frerichs: "Every diabetic must sooner or later, in consequence of loss of health and strength, run a risk of sudden and unexpected death. He is like a weary wanderer in a thick mist following a narrow path by the side of a roaring torrent, into which he is in danger of falling if he anxiously quickens his pace or strikes against a stone in the way." This by no means exaggerates a danger which cannot be foreseen or prevented by any care on the part of the patient or the practitioner in attendance. The author quotes a good illustrative case from Spitzer: A patient with slight diabetes under treatment at Carlsbad thought some one was coming into his bath-room, and in rushing to bolt the door fell and broke his collar-bone. He became very excited; the sugar went up to ten times what it had been; diacetic acid and acetone, which had been absent, appeared in large amounts, and in four days he died of coma. An even better illustration of the slight disturbance which may suffice is the case given by von Noorden of a merchant who presided for three hours at the general meeting of a large company; an hour later he became comatose. The treatment of diabetic coma upon which Dr. Magnus-Levy insists is the injection of sodium bicarbonate in 3 to 5 per cent. solution into the veins; the quantity of the injection should be about a litre, and it should be run in slowly, in from a quarter to half an hour. He thinks enemata are not so efficient, as they are not retained sufficiently long. If the patient shows any sign of recovery so that he can swallow, a teaspoonful of sodium bicarbonate dissolved in water or milk should be given every hour or half-hour, and he should be encouraged to drink large quantities of milk or soda water or mineral water. The great diuresis thus produced helps to clear out the acid. If the patient recovers, the diet for the first week should contain carbohydrates, and the quantity of sugar should be regarded as of secondary importance, but after this he must return to the diet on which he formerly was. Experience shows that it does not do to relax the dietetic treatment. The last part of Dr. Magnus-Levy's work discusses the diet to be used in severe cases of diabetes; he is emphatic as to the need for taking large quantities of fat, and he advocates the use of alcohol, 2 oz. to 3 oz. of spirits daily. He thinks von Noorden's oatmeal diet worth a trial, although it is difficult to find an explanation. He also urges that the patient should continue to use sodium bicarbonate regu-

larly. The result of the treatment recommended, it is admitted, is not very brilliant. Naunyn has had five recoveries, all in children, and Grube one case in a man over 50. No doubt numerous slight cases of threatened coma have recovered under it, but such have recovered under all kinds of treatment, and the diagnosis must always remain in doubt.

BIOCHEMISTRY.

The idea of issuing monographs or separate chapters on biochemical subjects is excellent, and if all of those promised are as good as the first, the editors of the series, Drs. ADERS PLIMMER and HOPKINS,⁴ will have no cause to regret their venture. It is a method of publication which might be followed with advantage in other rapidly growing branches of science, for each monograph can, if new editions are necessary, be issued independently of the rest, and the moderate price charged will enable those interested in one or more particular subjects, to get the most recent knowledge without having to pay for an expensive volume which may contain much of what is uninteresting to them, or which, owing to the scarcity of the demand, may not be fully up to date. Dr. BAYLISS's original work on enzyme action is of the highest character; it is therefore fitting that he should have been selected to write the first monograph of the series. Even the elementary student of physiology knows the important part played by enzymes in the chemical transformations which accompany vital activity, but it is only within recent years that the laws of fermentation have been understood, because it is only within that time that convincing proofs have been adduced that the laws they obey are those of catalytic phenomena. So exact is the increasing knowledge that has followed this discovery that it is now possible in many cases to treat the subject mathematically. This, however, need not deter the student from reading the book, for the subject is dealt with in an admirably lucid manner, and the book can be most warmly recommended to all those desirous of obtaining the latest information on a subject the importance of which it is not possible to overestimate.

The editor of the *Handbuch der Biochemie*⁵ is as good as his word, and the fasciculi of his book are appearing with great celerity. They are not published in the order in which they will subsequently be bound together, but the wise course is being pursued of printing the articles which are ready. The third fasciculus, for instance, begins volume ii, treating of the blood and lymph; the fourth and sixth fasciculi continue the first volume, although they do not complete it; and the fifth fasciculus starts the fourth volume, which deals with metabolism. It is unnecessary to repeat what we have already stated regarding the high standard aimed at, which is admirably maintained in the articles now before us. The later volumes deal with the more biological aspect of the question, the earlier ones with the more strictly chemical side. It may, however, be convenient for our readers and prospective purchasers of the various parts to enumerate the articles and their authors. In the fourth and sixth fasciculi Dr. F. SAUNELY completes his article on the proteins, and contributes three more on proteoses and peptones, animal ferments, and animal toxins respectively. Professor ABDEKHALDEN contributes an article on the hydrolysis of proteins, a subject which he of all others is qualified to treat authoritatively. The nucleo-proteins and their decomposition products are dealt with by Drs. A. SCHITTENHELM and K. BRAHM. The third fasciculus, which consists of the first 160 pages of the second half of vol. ii, contains six articles; the first is on the physical chemistry of the blood, by Dr. R. HOBER of Zurich; the second and third are written by Dr. P. MORAWITZ of Heidelberg, and deal with blood coagulation and plasma and serum respectively; the fourth is on lymph formation, by Professor R. MAGNUS of Utrecht; and the two last, on the chemistry of lymph, and on transudations and exudations, are from the pen of Dr. H.

³ *Das Komma Diabetikum und Seine Behandlung.* Von Dr. A. Magnus-Levy. Berlin. Halle a.-S.: Carl Marhold. 1909. (Med. 8vo, pp. 54. M. 1.40.)

⁴ *Monographs on Biochemistry.* Edited by R. H. Aders Plimmer and F. G. Hopkins. *The Nature of Enzyme Action.* By W. M. Bayliss, D.Sc., F.R.S., Assistant Professor of Physiology, University College, London. London: Longmans, Green, and Co. 1908. (Royal 8vo, pp. 120. 2s.)

⁵ *Handbuch der Biochemie des Menschen und der Tiere.* Edited by Dr. Carl Oppenheimer. Fasciculi 3 to 11. Jena: Gustav Fischer. 1908. (Sup. roy. 8vo, pp. (L. 3) 521, (L. 4) 320-400, (L. 5) 1120. Pro. 1/6, M. 5.)

Gerhardt of Berlin. The fifth fasciculus deals with gaseous metabolism, and contains, in addition to an introductory note by Professor N. Zant, two articles on that subject by Dr. A. Loewy of Berlin. The seventh fasciculus contains and completes Dr. Loewy's article, Gaseous Metabolism, and contains also a chapter dealing with metabolism during inanition by Dr. Brugsch of Berlin. Fasciculus 8 brings us back once more to volume ii. It treats of the physical biochemistry of cells, and contains four articles—two by J. Loeb, one by K. Spiro, and one by M. Jacoby. The ninth fasciculus starts the first half of the third volume, and deals with secretory glands and their secretions. Thus F. N. Schulz deals with mucous glands, salivary glands, and saliva; J. Plesch with sputum, A. Bickel with the gastric juice, Th. Brugsch with the secretions of the small intestine, S. Rosenberg with the pancreas, and J. Wohlgemuth with the liver and bile. Fasciculus 10 contains a bit of volume ii and part of the second half of volume iii. Its articles are on the chemistry of transudations and of the blood-forming organs, by H. Gerhardt; on the connective tissues, by H. Aron and F. N. Schulz; on the chemistry of foods, by F. Tangl; and on digestion in the mouth and stomach, by E. S. Loudon. The eleventh fasciculus contains a batch of articles on metabolism, A. Magnus-Levy taking the carbohydrates, and, in conjunction with L. F. Meyer, the fats as well; whilst R. Rosemann deals with the much-disputed question of alcohol. Nine more parts are yet to come, but one can begin to see now the general plan of the book and admire the wide and far-reaching underlying ideas that have guided its editor.

CLINICAL DIAGNOSIS: NEW AND OLD.

DR. J. CAMPBELL TODD'S *Manual of Clinical Diagnosis*⁶ aims to present a clear and concise statement of the more important laboratory methods which have a clinical value and to be a brief guide book to the interpretation of their results. It is designed for the student and practitioner, not for the trained laboratory worker. It follows on the lines of the well-known textbooks of v. Jaksch and Simon, but, unlike them, it has the special virtue of shortness and compactness. The methods selected are the more practical, and of them preference is given to those which require the least complicated apparatus and the least expenditure of time. The value of the book is increased, and at the same time its shortness and simplicity assisted by a large number of excellent illustrations. The author claims that practically all the microscopic structures mentioned, all apparatus not in general use, and many of the colour reactions are shown in the pictures. The seven chapters include the use of the microscope, the sputum with the methods of its bacteriology, the urine with the use of the centrifuge, the blood with its research methods and coloured representations of stained films, the gastric and intestinal contents with coloured pictures of their test tube reactions, and animal parasites. The book may be heartily recommended.

A little less than two years ago we received the first edition of *Clinical Diagnosis*, by Dr. C. P. EMERSON,⁷ and now welcome the second, more especially as some obvious defects in the first have been corrected and much new matter incorporated. The volume is admirably adapted to the needs of the laboratory worker, and is well indexed. Moreover, the illustrations are not only very accurately drawn, but are most beautifully executed. As an indication of the change made in the second edition, it may be said that the author has found it necessary to rewrite fully half the work. Much new matter has been added, moreover, and we are pleased to note that this is concerned rather with the bacteriological investigations which have of late years made such rapid strides, than with the more refined investigations of chemical pathology. We had reason to complain of the overloading of the first edition with the latter to the neglect of the former, and are most willing to acknowledge that Dr. Emerson has corrected

what was an obvious blemish in an otherwise admirable work by the inclusion of the bacteriology of the sputum and urine. Moreover, two most useful sections are contributed by Dr. Wm. L. Moss, the one giving a full and reliable guide to opsonic investigation, and the other a short but nevertheless correct account of the new method of substantiating the reaction of the body to bacterial infection—namely, by fixation of the complement. If only by reason of the inclusion of these two sections, the second edition is a great advance upon the first.

Dr. JOHN C. DA COSTA, jun., has written a book entitled the *Principles and Practice of Physical Diagnosis*,⁸ which, having regard to the limitations of the ground covered, may fairly be called exhaustive. It is of set purpose limited to a consideration of diseased conditions of the thoracic and abdominal viscera, and hence takes no account of diseases of the nervous system, blood, skin, or urinary system. As he says, Dr. da Costa chooses to make it deal purely with the theory and practice of physical diagnosis at the bedside with reference to the study of thoracic and abdominal lesions alone. It is so full of material, and almost always very good material, that it cannot be discussed in detail. To classify its subject matter on an academic basis it may be said that it is mainly concerned with clinical anatomy, the origin, mechanism, and significance of normal physical signs, and with a really thorough discussion of applied pathology and of diagnosis. It consistently interprets morbid objective clinical facts on the basis of pathological cause and physical effect. Methods of physical examination, including the more important instrumental procedures, are clearly described. It may remind some of Dr. Gee's well known book, but is less sententious and much inferior in its literary style, which is often ponderous and involved. It contains many most excellent illustrations. It includes reference to recent methods, not only well-established ones like those of sphygmomanometry, but such as is called in the book "erioscopy"—the digestion *in vitro* of coagulated pleuritic fluid followed by centrifugalization and subsequent bacteriological examination, a recognized method in the diagnosis of tuberculous pleurisy. By way of adverse criticism it might fairly be said that the book is overloaded, that it contains too much reference to named varieties of signs—for example, on page 455 there are no less than four: to wit, Drummond's, Sansom's, Glasgow's, and Galvagni's, all in the space of eight lines—and at the same time that there is not enough of critical appreciation of their significance or validity or the lack of it.

The appearance of a third edition of Dr. LESLIE THORNE'S THORNE'S little book on *The Naheim Treatment of Diseases of the Heart and Circulation*⁹ is sufficient indication that it has proved useful. The chapters on the preparation of the baths and the administration of the exercises—that is to say, the whole of the practical and special matter—has been revised. The photographs illustrating the exercises are very helpful in following the description in the text, and with their aid it should be possible for any one to carry out the instructions. The record of some cases illustrating the success of the treatment completes the volume.

TUBERCULOSIS, TREATMENT AND PATHOLOGY. The practical results of the world-wide campaign against consumption cannot as yet be estimated, but the campaign goes on with vigour, and the series of lectures delivered by Dr. Louis RENOX at the Hôpital de la Pitié in Paris¹⁰ proves that the subject is being pursued with energy in the French schools. Essentially practical in their scope, they present the matured experience of their author, together with his shrewd analysis of contemporary teaching, expressed in clear and simple language, which, to the English reader at any rate, adds in no small degree to the

⁶ *A Manual of Clinical Diagnosis*. By J. Campbell Todd, M.D. Philadelphia and London: W. B. Saunders Company, 1908. (Post 8vo, pp. 319; 131 illustrations. 10s.)

⁷ *Clinical Diagnosis: A Textbook of Clinical Microscopy and Clinical Chemistry for Medical Students, Laboratory Workers, and Practitioners in Medicine*. By Charles Phillips Emerson, B.M., M.D., Associate in Medicine, The Johns Hopkins University. Second Edition. Philadelphia and London: J. B. Lippincott Company. (Roy. 8vo, pp. 535, 5 plates and 125 figures, some coloured. 21s.)

⁸ *Principles and Practice of Physical Diagnosis*. By John C. da Costa, jun., M.D. Philadelphia and London: W. B. Saunders Co. 1908. (Med. 8vo, pp. 548, 212 illustrations. 15s.)

⁹ *The "Naheim" Treatment of Diseases of the Heart and Circulation*. By Leslie Thorne Thorne, M.D. Third edition. London: Baillière, Tindall, and Cox. 1909. (Cr. 8vo, pp. 94, 58 illustrations. 3s. 6d.)

¹⁰ *Le Traitement Pratique de la Tuberculose Pulmonaire*. By Dr. Louis Renon, Physician to the Hôpital de la Pitié, Paris. Paris: Masson et Cie. 1908. (Fcap. 4to, pp. 250.)

pleasure of their perusal. The complete failure of all attempts to destroy the tubercle bacilli *in situ* has been followed by no less vigorous efforts to neutralize the poison which they produce by means of serum and tuberculin and certain drugs. For almost all of these an initial success of something between 60 and 70 per cent. has been claimed by those who have used them in the first instance, but it is only too obvious that not one of them has hitherto achieved such results in the hands of the profession at large as to justify their general adoption. This forms a striking contrast with the universal recognition that welcomed the introduction of the antitoxin of diphtheria. Dr. Rénon points out that the normal ratio of improvement under the simple hygienic treatment of consumption stands at nearly the same figure as that claimed for any specific method, and if the influence of the psychic element be excluded there remains a very small balance in favour of the antituberculous properties of any of the suggested remedies. After close examination of all those that have been recently introduced, many of them within the last twelve months, he does not speak enthusiastically of any. The tuberculin prepared at the Pasteur Institute would appear to be giving good results, but the author wisely maintains that at least four years' experience of it is needed before trustworthy conclusions can be drawn. Of the uses of psychotherapy he has much to say, and his close observation of the state of mind of the French consumptive at various stages of his illness is very interesting. Much attention is also paid to the question of personal hygiene, and the restrictive effect of rigid rules applied to all cases is condemned. The enforcement of a "time-table" is perhaps necessary in a large institution, but in private the personal needs of individual patients must be studied. In a lecture devoted to dietetic treatment the importance of co-operation between the doctor and the cook on the patient's behalf is demonstrated. This point is too little regarded in this country, where culinary matters are so seldom the subject of ordinary discussion. The growth of knowledge and of interest with respect to the phenomena of gastric digestion will doubtless bring the science of cookery more to the front in the near future. Dr. Rénon has no faith in the doctrine of excessive alimentation for consumptives, and, like some other recent authorities, throws considerable doubt upon the value of fat in the dietary, and, incidentally, upon the utility of cod-liver oil. He records an interesting and convincing series of experiments on guinea-pigs which go to prove that the addition of butter to a fixed diet caused marked lowering of their powers of resistance to the ravages of artificial tuberculosis, as against exactly similar experiments with sugar and gluten respectively. Of drug treatment he maintains that the primary consideration should be to do no harm. The value of calcium salts is extolled, and the uses of many drugs for the relief of symptoms are mentioned. Some of these will be unfamiliar to English readers. Faith in their efficacy both on the part of the patient and of the physician is regarded as the essential element of success. Climatic and other accepted lines of treatment are duly passed in review, and a chapter is devoted to the means of dealing with consumption when complicated by other morbid conditions. As a sound, common-sense account of the present state of the therapeutics of consumption we can cordially commend these very readable lectures.

Dr. BONNEY in *Pulmonary Tuberculosis and its Complications*¹¹ writes mainly from the clinical point of view, and primarily for the benefit of the practitioner rather than for the scientific inquirer. Colorado, where Dr. Bonney has gained much of his experience of the disease, furnishes good scope for clinical observation since it is much frequented by the consumptive in search of health. That Dr. Bonney has had much practical experience of the subject is apparent throughout the book, and gives it a special value. The illustrations are numerous and useful; by making use of photography to show the various types of chest conformation, and alterations in appearance due to disease, we get the idea of actuality which fits the text—the sense that we are sharing the results of the author's experience and not merely perusing a compilation from other writers. We may not always agree with the author's

views or accept all his deductions, but it is useful and interesting to learn what his experience has taught him. Though the major portion of the book is essentially clinical, the preliminary chapters are devoted to etiological considerations. The review of the differences between the human and bovine types of the *Bacillus tuberculosis* may be noted as particularly lucid. A large amount, as appears to us an undue amount, of space is devoted to a general review of the methods of physical examination of the chest. That there is much concerning physical examination of which the average practitioner requires to be reminded as a preliminary to the clinical study of chest diseases may be admitted, but in the sixty-three pages here devoted to physical examination there is much which belongs to the earliest training of the clinical student, and therefore somewhat out of place in a special work on tuberculosis. There is a very good chapter, illustrated with an excellent series of x-ray photographs, on the assistance to be derived from the Roentgen rays in defining the lesions in pulmonary tuberculosis. Dr. Bonney is evidently amongst those who do not look to the radiograph to obtain the earliest signs of commencing tuberculosis in the lung, for he says (p. 252): "A structural lesion sufficient to show a distinct shadow change is often preceded by such subjective and objective signs as will warrant an unqualified diagnosis." A large part of the book is devoted to the complications which may arise in the course of pulmonary tuberculosis; the treatment of the primary disease and of the various complications is fully discussed. In the section on the treatment of hæmoptysis, which is very sound in principles and very practical, we find with the more recent remedies which are advocated some traditional practices not now universally accepted. Amyl of nitrite is recommended—though in smaller quantities than we have found to be efficacious. On the other hand, the icebag applied to the chest and a strictly recumbent position for the patient in the routine fashion which used to be recommended have now been discarded by many practitioners. Dr. Bonney, however, notes that more importance may be attached to the position of the icebag over the cardiac area than over the supposed site of the hæmorrhage. In this section there is apparently a misprint in the extract which follows, the word which we have italicized being obviously not what was intended. On p. 715 we read: "Conversation in the room should be strictly enjoined, the patient being addressed only when necessary." As it is expressly stated on the previous page that it is essential that no person should be allowed in the sick room besides the nurse, it is evident that conversation is not "enjoined." Dr. Bonney's book is one which should soon reach a second edition: this is our justification for picking out from so large a mass of good work some small subjects for criticism.

The discovery of the tubercle bacillus in 1882, and the instant confirmation of its universality, carried all before it, and the views of the older observers as to the so-called inflammatory origin of the disease were swept away with more or less contempt. Time, however, has served to show that the bacillary theory is not all-satisfying, and the physiological aspect of tubercle formation has been found worthy of study from other than the bacillary standpoint. Dr. CHARLES CREIGHTON in a recent book¹² has put forth the results not only of a careful analysis of the works of others in the same field, but also an interesting account of his own experiments and observations, extending over a considerable period, and giving evidence of very careful thought and study. Although there is unanimity in acceptance of the tubercle bacillus as the primary cause of tubercle, the whole subject of the histogenesis of the morbid changes is "beset with difficulties and paradoxes." The changes of opinion on the part of Koch himself respecting bovine and avian tuberculosis, the experiments of Wooldridge and others to prove that substances such as tissue fibrinogen might produce lesions indistinguishable, histologically, from those produced by the bacillus, all tend to prove that the whole truth is not yet known, and that the subject calls for closer examination. In this handsome volume, illustrated by explanatory drawings of microscopic specimens, Dr. Creighton accordingly sets forth a full account of the histogenesis

¹¹ *Pulmonary Tuberculosis and its Complications*. By S. G. Bonney, A.M., M.D. Philadelphia and London: W. B. Saunders and Co. 1908. (Roy. 8vo, pp. 784. 30s.)

¹² *Contributions to the Physiological Theory of Tuberculosis*. By Charles Creighton, M.D. London: Williams and Norgate. 1908. (Roy. 8vo, pp. 252; 64 illustrations. 12s. 6d.)

of experimental tubercle, giving a historical epitome of the labours of the pre-bacillary pathologists, and a detailed account of his own observations on this part of his subject. He then considers the placental analogies of the tuberculous neoplasm as seen in the rodent, the third part of the work being devoted to an examination of human and bovine tuberculosis, especially in relation to its manifestations in lymph glands, serous membranes and meninges. The text of the whole may be found in the caustic observation of the author in relation to Koch's dictum that the discovery of the bacillus and not the histological conditions must in future be the criterion of tubercle. It is, he says, "a very simple criterion, much appreciated by those who have little time to think, or no great turn that way." That he has allowed himself plenty of time to think is evident throughout the work, but it is perhaps to be regretted that he has not found a simpler method of expression for his thoughts. The reader will need plenty of time to unravel some of them. To follow in detail the various steps of his argument is beyond the scope of an ordinary review, and it must suffice to record that the author regards the histological changes as being due primarily to the action of the poison upon the red blood cells. Thrombosis of minute vessels is the initial lesion, with plasmodial organization of the thrombi and a building up of a nuclear protoplasm from blood discs in the capillary walls and cavities of air cells when the disease affects the lungs. The neoplasm thus built up serves to get rid of the waste of disintegrated or reduced red blood corpuscles. The evidence upon which his arguments rest must be studied in the original work. Using the analogy of the placenta, he labours to prove that the histogenetic changes known to be produced by the injection of tubercle bacilli are the same as may be found under certain physiological conditions. Turning to the comparison of bovine with human tuberculosis, he emphasizes the histological peculiarities of the former and the initial occurrence of thrombosis—"but for the thrombosis there would have been no tubercle, and but for something in the blood there would have been no thrombosis." The whole work is worthy of the attention of investigators in the pathological laboratory, and although it may be thought that the accuracy of observations made so long ago as 1846 to 1889 may be open to question, still the specimens and drawings of that day remain in evidence, and modern observers cannot ignore the facts that they demonstrate, however much the interpretation may differ.

NOTES ON BOOKS.

THE *Minutes of the General Medical Council and of its various Committees for the year 1908, with fifteen appendices*, has been issued. It is the forty-fifth volume of the series, and contains 664 pages, being 242 in excess of that for the previous year. The minutes of the General Council occupy 150 pages, of the Executive Committee 75 pages, of the Dental Committee 18 pages, and of the Branch Councils 17 pages; the remainder of the volume is occupied by fifteen appendices, being reports of various committees. There has also been issued the *General Index to the Minutes of the General Medical Council, of its Executive and Dental Committees, and of its three Branch Councils. Vol. XL to XLV (1903-1908)*, which will be of great assistance in looking up references with regard to the procedure of the Council or its committees in any of the matters considered during the period. In 1903 an index of the Council's minutes for the previous years was published, and this proved so useful that it was decided to publish an index at shorter intervals: at the meeting of the Executive Committee on May 25th, 1908, it was resolved that the new volume should be kept in type and brought up to date year by year.

The *Schoolmaster's Year Book and Directory for 1909*¹ is the seventh annual issue. It consists of three parts. The first contains official particulars as to the administration of secondary education: a list of educational societies and organizations, including county education committees; condensed particulars as to universities, colleges, and medical and other schools; official particulars as to

examinations and inspections: a chronicle of the year, containing events of the year in chronological order and also classified under subjects; and a review of the year, which discusses many subjects of interest to masters of secondary schools. The second part is a directory of schoolmasters, and the third an alphabetical list of secondary schools. In the first part there is a short section on examinations preliminary to the professions, which, judging by the particulars given as to medicine, must be pronounced quite insufficient as a guide either to master or parent.

TEXTBOOKS OF MEDICINE.

DR. ARTHUR R. EDWARDS of Chicago has written an excellent *Treatise on the Principles and Practice of Medicine*.¹ In form and scope it corresponds very closely with other well-known American textbooks on medicine, but among the characteristics which the author has endeavoured to impress on it are the blending of causative pathology with the consecutive clinical features of disease, the subordination of exceptions to what is usually found at the bedside, and the discounting of typical clinical pictures and other dogmatic generalizations. An unusual amount of space has been devoted to treatment, acting on the excellent general principle that the final object of the existence of a book on practice is the application of knowledge to the cure or alleviation of disease. Leaving generalities, it may be especially noted that the book contains a really helpful chapter on septic affections, several good and comprehensive tables of the differential diagnosis of disease, of which that referring primarily to typhoid fever is a good example, and many new and useful illustrations, among which may be mentioned the clumping of typhoid bacilli, Koplik's spots—of course, in colour—stained pneumococci, crystals of phenylglycosazon, plates of blood films illustrating on one page some eight or nine different blood diseases, and drawings of changes in the fundus oculi met with in different diseases, all also in colour. Not only are pneumonia and tuberculosis classed with the acute specific fevers, but acute rheumatism likewise. That this textbook will rank with the better may confidently be predicted.

The short *Practice of Medicine*² by the late Professor CHARLES has reached a ninth edition under the editorship of Dr. F. J. CHARLIS. The original plan of the book has been maintained, but extensive alterations have been made so as to bring the book up to date. Several of the articles on fevers have been rewritten by Dr. A. Gray Banks, who has had special experience, and this co-operation is to the advantage of the readers of the book. In addition to substantial alterations in the old text, some forty morbid conditions have been for the first time included, such as mucous colitis, duodenal ulcer, heart-block, and fibrositis. These inclusions and other additions have naturally increased the bulk of the text, but by using a slightly larger page and by omitting the introductory chapter on general pathology the book is only some thirty or forty pages larger than the former edition, although its scope is so considerably extended. A feature of the book is an appendix consisting of a therapeutical index, a section on baths, one on vaccine treatment, one on prescriptions and prescription writing, and a series of formulæ for different medicines. Following these is a section on the method of performing post-mortem examinations and a glossary of medical terms. The book is obviously meant as a primer for men beginning the study of medicine proper, and as such it may be recommended.

After an interval of seven years appears a new edition, the sixth, of the late Dr. Husband's handbook on the *Practice of Medicine*.³ It is rather a rewriting than a revision that has been undertaken, but the well-known characteristics of the book have been preserved. Dr. ROBERT A. FLIMING has written the sections dealing with treatment and also all those dealing with diseases of the nerves; for the rest of the book Dr. R. F. C. LEITH is responsible. A sign of the times is that there is no separate section for diseases of the spleen. There is an excellent index.

METHODS OF QUACKERY.

ALL THE ILLS OF HUMANITY.

ALTHOUGH it appears that persistent advertising and some ingenuity suffice to enable many makers of quack medicines to foist one preparation on to the public as a remedy for many and diverse diseases, the large possibilities in professing to treat all complaints, on the patient's own description alone, by medicines "specially prepared" for the individual case, have not escaped attention. We have before us a paper-covered book of some hundred pages, entitled "The Ills of Humanity by Dr. James W. Kidd, Fort Wayne, Ind.," together with letters from "The J. W. Kidd Co.," sent to an applicant for further information, which furnish a striking example of the variety of quackery we have referred to, and appear to merit publicity.

We commence with some extracts from an advertisement which appeared not long ago in a London weekly paper:

Free! Free!

To the Sick and Ailing Everywhere.
The Cure for your Disease—Delivered Free—Free for the Asking—Free to You.

To the sick—the suffering—to every man and woman victim of organic disease—local trouble or broken general health—Dr. Kidd's offer of free treatments is given in the absolute faith and sincere belief that they can and will stop disease, cure it, and lift you up again to health and vigour.

Rheumatism, kidney trouble, Bright's disease, diabetes, heart disease, partial paralysis, bladder troubles, stomach and bowel troubles, piles, catarrh, bronchitis, weak lungs, consumption, asthma, chronic coughs, nervousness, all female troubles, humpago, skin diseases, scrofula, impure blood, general debility, organic vital ailments, etc., are cured to remain and continue cures.

Will you let me do this for you—will you let me prove it—brother and sister sufferers? Are you willing to trust a master physician, who not only MAKES this offer, but PUBLISHES it and then sends the test and proof of his remedies without a penny of cost to anyone except himself?

My home office is at Fort Wayne, Indiana, U.S.A., but for the benefit of my thousands of English patients, I have established an office in London. Please address Dr. James W. Kidd, "Box" No. 104, 36 St. John Street, Clerkenwell, E.C.

The advertisement is accompanied by a cut of a man's head, presumably the "master physician" in question. In the book referred to above, a portrait of "Dr. James W. Kidd" is given, and the two seem to represent totally different persons. In the book there is an introductory paragraph on "Dr. James William Kidd"; in it we read:

His profound knowledge of medicine, his remarkable power over disease, the honesty and wisdom of his business methods are best proven by his wonderful success. The enormous practice which he has built up in a comparatively few years is without doubt larger than that of any single physician in the world to-day.

The first and most important reason why you should patronize Dr. Kidd is because he has had a long and varied experience and the most gratifying success in his practice. During the past two years alone he has expended over three hundred thousand dollars in advertising his now justly famous remedies.

... at the present time, Dr. Kidd has among his resources remedies that enable him to treat successfully many diseases that are generally considered incurable.

Unlike the majority of physicians, Dr. Kidd does not confine himself to the methods of any one school of medicine. He does not hesitate to take advantage of any method or curative agency that promises to benefit his patients.

The book is principally occupied with a series of paragraphs on different complaints, rather over a hundred being dealt with; in the majority of cases the description leads up to reference to Dr. Kidd's treatment, or medicines, etc.

It appears that persons writing to "Dr. Kidd," or the company, receive a "Self Examination and Consultation Blank." This commences with spaces for name, address, age, and occupation, and continues as given below. The words here printed in italics are the answers supplied by the hypothetical patient who has sent the Blank to us, and are supposed to refer to the case for which the medicines described below were sent:

1. Do you have rheumatism? *Yes.*
2. Do you have dropsy? *Yes for 2 years.*
3. Do you have scrofula or other blood poisons? *Yes.*
4. Do you have heart trouble? *No.*
5. What name do doctors give your disease? *Very difficult to diagnose.*

6. Is your hearing failing? *Yes.*
7. Does your nose discharge? *Yes.*
8. Is your sense of smell leaving? *No.*
9. Is there a dropping into your throat? *Yes.*
10. Do you cough? *Yes.*
11. Do you have pains in the chest? *Sometimes.*
12. Is your sputum (spit) streaked with blood? *No.*
13. Do you have asthma? *No.*
14. Is your appetite good? *Indifferent.*
15. Do you have a burning sensation in the stomach? *No.*
16. Do you have sour risings (belchings)? *Yes.*
17. Are you constipated? *No.*
18. Do you have diarrhoea? *No.*
19. Are you troubled with piles? *No.*
20. Is your liver torpid? *Yes.*
21. Do you have pain in the small of the back? *Yes.*
22. Do you have frequent desire to urinate? *Yes, very.*
23. Does your urine scald you? *Yes.*
24. Do you have pain in the region of the bladder? *No.*
25. Do you have to rise at night to urinate? *No.*
26. Have you any skin disease? *No.*
27. Of what nature?
28. Is your circulation poor (numbness)? *Yes.*
29. Are you troubled with neuralgia? *Yes.*
30. Are you nervous? *Yes.*

Further sections are added headed, "For Gentlemen only" and "For Ladies only," for information about disorders confined to one sex.

The answers given above were sent in, and the following was received in reply:

Diagnosis and Case Record.

By Dr. James W. Kidd, Fort Wayne, Ind.
For a complete description of your case, the probable results and my method of treatment, see pages 46, 99, 23, 13, 9, of the pamphlet "The Ills of Humanity," sent you under separate cover.

I find that you are afflicted with Rheumatism, Scrofula, Catarrh, Dyspepsia, and Gastritis.
Rheumatism MEANS an excess of uric acid in the blood.
Scrofula is a constitutional disease almost synonymous with tuberculosis.

Catarrh is an excreting inflammation of the mucous membrane.

Dyspepsia (Indigestion) MEANS impaired secretion of pepsin and consequent imperfect digestion.

Gastritis MEANS catarrh of the mucous membrane of the stomach.

TAKE THE REMEDIES ACCORDING TO THE FOLLOWING DIRECTIONS:

- One Tablet "A" before breakfast.
- One Tablet "B" before dinner.
- One Tablet No. 13 before supper.
- One Tablet No. 7 after dinner and after supper.
- One Tablet No. 45 on retiring.

This was accompanied by tablets marked "A," "B," and "13," three of each, four marked "45," and five marked "7"; also by a letter which is worth reproducing in full; this appeared to be lithographed, and although the name and address were in the same writing and the same ink, they showed evidence of having been added afterwards. It seems probable, therefore, that, although professing to be a personal letter, it is one in regular use. The "special interest in your case" is a familiar feature in quacks' letters.

Dear Friend:—

In compliance with your request received to-day I have prepared and forwarded to your address under separate cover, a sample of the remedies as promised. As the drugs are very expensive and we are required to send out hundreds of samples each day, it is impossible to send larger amounts. I trust, therefore, that you will take into consideration the fact that you cannot expect any remarkable results from the sample, but we desire mainly to call your attention to the neatness and elegance of our preparations, and their adaptability to the most delicate stomach, especially if you are one of the many who have had discouraging experience with the nauseating liquids, bitter and disagreeable powders, tablets and pills, usually found in drug-stores. I have taken special interest in your case, because I want a cured patient in your immediate vicinity. This is why I have gone to the trouble of writing you a personal letter.

After making a careful diagnosis of your case (see type-written copy enclosed in this letter) I find that it is very complicated and severe, and will require several special remedies to effect a cure. These special remedies are very expensive, but I have decided to quote you a very low price on the complete treatment.

Believing that you are anxious to be cured at the earliest possible moment, to avoid unnecessary delay, I have to-day selected and will forward to your address upon receipt of your remittance of £1 the complete course of treatment. Do not become discouraged if you have failed to obtain relief from local doctors or patent medicines. I am not a local doctor and the remedies I am offering you are not patent medicines,

but a course of treatment carefully selected to meet the requirements of your case.

I feel sure that I can restore you to health. In making this statement, I base my opinion on the results obtained in many similar cases that have come under my treatment. Much depends on taking the case in time. Every day's delay increases the difficulty of effecting a cure. I trust, therefore, that you will order at the earliest possible moment.

In ordering, please give me any further information concerning your case that you may deem important. If this develops the fact that any additional remedies are needed they will be included without extra cost.

Remember also, that you are entitled to my services entirely free while you are under treatment.

Awaiting your order and assuring you of my prompt and careful attention at all times, I remain,

Yours Very Truly,

DR. JAMES W. KIDD.

It would appear that the "personal attention" given to each case is of the most mechanical nature. It is not necessary to point out the utter inadequacy as a means of diagnosis of the "Self-examination and Consultation Blank" given above; the answers on the Blank quoted were filled up in a manner which negated the possibility of a diagnosis being made. This, however, presented no difficulty. Five diseases are specified to account for the symptoms, five headings in the pamphlet sent are referred to, and five kinds of tablets were sent. These tablets were analysed as completely as was possible with the small quantities sent, with the following results:

Tablet A (triangular) was coloured externally with a salmon-pink dye; the outer coating was of sugar, and below this was a rather thick coating of chalk, forming a very hard and resistant covering to the tablet. The decoated tablets weighed about 3½ grains each; they contained 52 per cent. of sodium bicarbonate, and the remainder consisted principally of a bitter extract agreeing in all respects with extract of gentian; small quantities of potato starch and a substance of resinoid nature which could not be identified were also present. No other medicinal substance could be found.

Tablet B (triangular) was coloured externally with a bluish-purple dye; the coating and the material of the tablets agreed in all respects with *Tablet A*, and the two were evidently identical.

Tablet 18 (circular) was white; the coating was of similar composition to that of *A*. The decoated tablets weighed about 3.8 grains each; analysis showed the presence of about 1 grain of sodium benzoate in each, together with a small quantity of a greenish, moderately bitter resin which could not be identified, and a trace of oil of wintergreen. Faint indications were obtained of a trace of an alkaloid, but not enough to amount to positive evidence. No other medicinal substance could be found; the remainder was of "extractive" nature.

Tablet 45 (circular) was coloured externally with a pink dye; the coating was of similar composition to that of *A*. The decoated tablets weighed about 1.1 grain each; the chief constituent was aloes, and there was also present a very small quantity of ginger extract, and a small quantity of resin, which was probably jalap or scammony resin; also a moderate trace of alkaloid which was not the alkaloid of *nux vomica*, belladonna, or hyoscyamus, but was not present in quantity sufficient to be identified; the only other ingredient found was a little potato starch.

Tablet 7 (circular) was not coated. The average weight of these was 6.5 grains each, and they consisted principally of charcoal, with some sugar and a very little saccharin.

"These special remedies are very expensive"! (letter above).

The reply which was sent to this letter was not satisfactory to "Dr. Kidd," and elicited the following in return. The anxiety for a remittance is rather apparent.

Dear Friend:

I am in receipt of your brief communication and while I am pleased to hear from you, I regret to inform you that I do not quite understand your letter. I wrote you fully regarding your condition and sent you a trial treatment also requested you to make remittance, so that I could prepare and forward a complete course.

Now dear friend, I trust that you will comply with my request and make remittance at the earliest possible date. I have made a speciality of treating diseases of this nature for a number of years and have been very successful and have every reason to believe, therefore, that I can bring about a cure for you.

Should it be impossible for you to make a remittance I wish you would write me to that effect perhaps I may be able to give you advice that may be of great benefit to you.

Hoping that you will make remittance at an early date, assuring you of my prompt and careful attention, I beg to remain,

Sincerely yours,

DR. JAMES W. KIDD.

CONSUMPTION.

In the *BRITISH MEDICAL JOURNAL* of August 22nd last (page 506), in the course of an article on certain secret remedies for consumption, the results of an analysis of "Stevens' Consumption Cure" were given. It was stated that it was a clear red liquid, and that analysis showed it to contain, in 100 fluid parts, 21.5 fluid parts of alcohol, 1.8 parts of glycerine, and 4 parts of solid substance, which contained about 1 part of a tannin and 0.2 part of ash, the remainder being extractive. No alkaloid was present, and no other active substance could be detected. The solid substance agreed in all respects with the solids of decoction of *krameria*, or a mixture of this decoction with a little tincture of kino.

Mr. Stevens, in one of the circulars which he issues states that:

"The African herbs which my Cure is prepared from, have never been used by any white Doctor or Chemist before I introduced same to civilization a few years ago. These herbs are original and have defied our cleverest Analysts to discover the active principals (*sic*) they contain."

In the same issue we also quoted (page 518) from a circular letter which Mr. Stevens had recently sent out to medical practitioners, asking them to treat consumptive cases which defied all the ordinary remedies, with his secret preparation. The circular continued:

"The great drawback to my cure, so far as the medical profession is concerned, has always been the fact that I would not reveal its formula. This is now done away with; its formula is 80 grains of umckaloabo root and 13½ grains of chijitse to every ounce, prepared to *British Pharmacopoeia* methods."

The publication of the article drew from Mr. Stevens a letter addressed to the proprietors of the *BRITISH MEDICAL JOURNAL*, in which he asserted that the component parts of the remedy were truthfully and correctly stated in his circular. We had failed to discover any reference to the two drugs with these remarkable names in any available work on pharmacy, and ventured to express the opinion that the formula was a farce. At the instance of Dr. Rayner, Dr. Porter, Medical Officer of Health for Johannesburg, kindly enlisted the assistance of Dr. G. A. Turner, who made inquiries from natives of several races, and from experts in native matters, without being able to ascertain that the names were known. Information was also sought from Mr. Charles F. Juritz, D.Sc., Senior Analyst in the Government Analytical Laboratory, Capetown, who was good enough to communicate with the Secretary of the Native Affairs Department. That department instructed the chief magistrate of the Transkeian territories to cause inquiries to be made into the question whether the native tribes there resident had any knowledge of "umckaloabo" and "chijitse," or of their reputed medicinal properties. The result of the inquiry was entirely negative. Nothing was known of any such plants, nor was it even possible to identify their names. Smith's *South African Materia Medica* contains no record of any such names as "umckaloabo" and "chijitse."

THE annual meeting of the Certificated Dispensers' Association held at the Apothecaries' Hall, London, E.C., was well attended. The financial statement showed a substantial balance to the credit of the association. The honorary secretary reported that the membership had steadily increased, the number at the end of the year being 325, and congratulated the members on the acceptance by the Government, through the kind offices of Sir William Collins, M.D., M.P., of an amendment securing the inclusion in Clause iv of the Poisons and Pharmacy Bill of holders of the certificate of the Apothecaries' Society. A register kept by the secretary had been the means of providing many members with temporary and permanent appointments.

BEER, AND THE MATERIALS USED IN ITS PRODUCTION.

It is a matter of common knowledge that beer, in its several varieties, is by no means the same thing to-day as it was a generation or less ago; the progress of chemical and biological knowledge on the one hand, and the keenness of competition on the other, have led to great alterations both in the materials used in its production and the methods by which it is produced. Exact or reliable knowledge about this, however, is far from being common; vehement assertions are made that all or almost all the changes are for the better, and also that beer is now a manufactured chemical product of deleterious nature, in which little or nothing of genuine material is used. Such statements are rendered unacceptable by the existence of self-interest on one side and prejudice on the other. A short account of some of the facts concerned may, therefore, be of service to the medical practitioner.

Chemistry of Brewing.

Beer is generally understood to be an alcoholic liquid brewed from malt and hops, the alcohol being produced in a fermentation process caused by yeast. In 1847 the use of sugar in addition to malt was permitted by law, and it was only so recently as 1880 that the employment of other substances was legalized. In its simplest form the production of beer is carried out as follows: Barley grain is steeped in water, then drained, and the moist grain kept for some days at a temperature of about 55° F., during which time germination commences; the grain is then kilned, or exposed to the heat from a slow fire, which stops growth, and the rootlets which had formed are removed; at this stage the grain constitutes barley malt. The malt is next ground, and is then mashed—that is to say, it is treated with hot water for some hours; the liquid is then run off, a variable quantity of hops added to it, and the whole boiled together for some time. The liquid is again run off and cooled, yeast is added to it, and the mixture is allowed to stand for some days; the yeast multiplies greatly, producing alcohol and carbonic acid, and using up the dissolved carbohydrate in doing so. When the fermenting action is at an end the liquor is separated from the yeast, and then constitutes beer.

The chemical changes involved in the process are many and complex; the principal are as follows: During the germination of barley two of the nitrogenous bodies known as enzymes—*cytase* and *diastase*—are produced; the former has the property of attacking and dissolving the delicate envelope of the starch granules, of which the grain contains a large proportion, and so rendering the contents of true starch accessible to the diastase; under the influence of the latter the starch assimilates water and becomes converted into soluble carbohydrates, principally dextrins and maltose (malt sugar). These soluble carbohydrates are required for the formation of the young barley plant; some of the proteid stored in the grain is also converted to soluble forms. When the germinating grain is kilned, its life is destroyed and these changes are arrested, but the *cytase* and *diastase* which have been formed remain in greater or less quantity, according as a lower or higher temperature is employed in the kilning. When the ground malt is mashed—that is, treated with water between 140° and 160° F.—these ferments resume their action on the starch, and at the end of the mashing the liquid (now termed the "wort") contains most of the carbohydrate of the grain in the form of dextrins and maltose, and a part of the proteid has also gone into solution; the residue left on running off the wort consists chiefly of the empty cell tissue of the grains. In the next stage, when the wort is boiled with hops, several changes occur; sterilization is effected, and part of the proteid is coagulated and precipitated; aromatic and bitter substances are dissolved out of the hops, which play an important part in giving the beer its flavour and also act as preservatives. During the several days' action of the yeast, most of the maltose is converted to alcohol and carbon dioxide, and the gradual increase of the alcohol and diminution of the sugars leads to cessation of the growth of the yeast, which separates either to the top or bottom. The beer can then be run off, and is ready for consumption; usually, however, it is

stored in casks for a longer or a shorter time, a further small quantity of hops being often added; during the storage a slow secondary fermentation is caused by the small amount of yeast remaining in it, improving the flavour and aeration.

Each stage of this process is capable of various modifications, causing variations in the product; also, almost every stage, as it has come to be understood, has presented the possibility of attaining the desired end, or some passable imitation of the desired end, by some other means than that originally employed, such other means either entirely replacing the original or being used as auxiliaries to it. To mention the variations first, the temperature at which the malt is kilned greatly influences the beer. Malt dried at a low temperature produces pale beer; that dried at a higher temperature gives a darker beer; the malt may also be roasted, like coffee, before mashing, and the very dark product then obtained is known as stout or porter. The quantity of hops boiled with the wort may be varied considerably, giving a less or a more bitter beer. The fermentation with yeast may be stopped while a good deal of saccharine matter still remains in the liquid, or may be pushed as far as possible, more or less "body" in the product being the result of such variations. When fermentation is conducted at a low temperature more sugar and dextrin will remain and less alcohol be formed; lager beer is produced in this way. The principal varieties of beer are thus as follows:

Mild ale, in which a low proportion of hops is used, and fermentation is continued until a low amount of solids remains.

India pale ale, which contains more hops than "mild."

Bitter ale, which contains more hops and also more solids than "mild."

Stout or porter, in which part of the malt is roasted; it contains a high proportion of solids, part consisting of caramel.

Lager beer contains more dextrin than English beer, and usually less alcohol.

The percentage of alcohol in beer varies considerably, according to the variety, and is usually between 4 and 7 per cent. by volume; but neither in regard to this nor to any of the properties just mentioned are there definite or binding limits, and the characters of any variety of beer or stout may differ considerably among the products of different brewers.

Substitutes for Malt and Hops.

As regards the employment of other materials than those mentioned above, it is not possible to condemn such a proceeding without qualification, while it is no less impossible to express entire approval of it. A Parliamentary Commission which reported on the subject in 1889 decided, after hearing the evidence of experts and others representing various points of view, not to recommend legislative restrictions on the materials used in brewing; a minority report, however, signed by only one member of the Commission, was in favour of restricting the name beer to a liquid brewed from malt and hops only. The employment of other materials is in many cases the normal result of a more scientific understanding of the processes in question, and a laudable desire to avoid the waste which occurred with the older empirical methods. But the desire to cheapen the production of beer by utilizing scientific knowledge has often led further, and, under the pressure of keen competition among brewers, has resulted in the employment of materials which do not yield the same product in a more economical manner, but which yield only a product not easily distinguished by the consumer from that of which it is an imitation. It is, then, at best highly debatable whether the cheaper imitation is as good as the older beer which it has displaced.

In answer to questions put in Parliament recently, the Chancellor of the Exchequer stated that the Board of Inland Revenue had refused its sanction to the use of malt and other materials containing arsenic in excess of the limit proposed by the Royal Commission on the subject, and also to the use of "heading" powders and liquids or other articles containing saponin, whether derived from quillaia or not, of flavouring essences, saccharin, sacrumine, and compounds containing saccharin. On the other hand, the following articles had come under the notice of the

Board as being used in the manufacture or preservation of beer, and had not been prohibited :

Rice, flaked rice, rice grits, rice malt, gelatinized rice, Maize, flaked maize, maize grits, maize flour. Oats—flaked, rolled, malted, and crushed. Torrefied barley.

Yeast foods.—These include solid and liquid preparations of peptonized yeast sold under various trade names, as nutriment, peptonide, dalline, etc., and mixtures of malt, flour and alkaline phosphates, common salt, etc., and preparations of malt combings, etc.

Preservatives.—Mainly sulphites of soda and potash, sold under various trade names, for example, kalium metasulphite (K.M.S.), sulphosite, etc. Salicylic and boric acids are also occasionally used as preservatives.

Burtonisers—(substances used for hardening brewing waters) are chiefly sulphates and chlorides of calcium and magnesium.

Neutralizers.—Mainly carbonates of potash and soda and sold under various trade names, as regenerator, acid neutralizer, antacid, etc.

Hop Substitutes.—Catechu or cutch, tannin, extrait de houblons d'Alsace, Davis's hop substitute, optanin, quassia, and preparations containing quassia.

Preparations used to precipitate albuminous matters from wort, mainly gelatine, Iceland moss, Irish moss, alginol, ibrite, etc.

Miscellaneous Brewing Materials.—Albumen, maltose, linseed, liquorice, amide syrup (ceramide), dextrin.

A few figures showing the extent to which some of these materials are used may be of interest. Brewers are required by law to keep full records of the principal substances employed in brewing, and the statistics so obtained are published annually. The figures here given are the most recent available; they refer to the year 1906-07, and are taken from Parliamentary Paper No. 32 of Session 1908.

Brewers who employ only malt and hops or hop substitutes constitute 44 per cent. of the total number of brewers licensed, but produce only 9 per cent. of the beer brewed in the country; of this quantity, over two-thirds—equal to 2,600,000 standard barrels—is the produce of a single firm; in 1900 the number of brewers in this class was 55 per cent. of the total of those licensed. The remaining 91 per cent. of the total beer produced is made by brewers who use malt substitutes as well as malt. Taking all the breweries in the country together, the total of malt and malt substitutes used is divided into:

Malt	76.55 per cent.
Unmalted corn	0.14 "
Rice, maize, and similar materials	6.46 "
Sugar and similar materials	16.82 "

In the hopping process the materials used are:

Hops	99.95 per cent.
Hop substitutes	0.05 "

The use of other materials than malt in the mash tun depends on two facts: first, the diastase of malt grain is capable of converting into soluble carbohydrate a larger amount of starch than is present with it in the grain; and second, yeast can act on other sugars than the maltose formed by the action of diastase on starch, and the two principal products of fermentation, alcohol and carbon dioxide, are the same, whatever the nature of the sugar employed.

The first of these facts permits of the use, in the mash-tun, of unmalted grain (which contains little or no diastase) of various kinds, the principal ones employed being barley, oats, rice, and maize; wheat, rye, sago, and potato starch are also used; when maize is used the germ is first removed, as it contains a good deal of oil which gives an unpleasant flavour to the beer and interferes with its brightness. The starch of any unmalted grain would not be acted on by the diastase of the malt unless the granules were previously burst, and unmalted grain must therefore be boiled before it goes to the mash-tun. This is often done in the brewery; but flaked rice, flaked maize, torrefied barley, and other materials consist of grain that has been moistened, heated sufficiently to gelatinize the starch, and again dried, before it is sold to the brewer. If the malt employed contains sufficient diastase, a very considerable proportion of rice or similar material can be employed; such "raw grain" may constitute 75 per cent. of the total taken for mashing. Most of the materials so used contain less nitrogenous substance than barley malt, and the wort is therefore poor in proteid

constituents; one result is that when the fermentation stage is reached the yeast will not grow well unless the deficiency is made good, and the "yeast foods" mentioned in the list given above are added for this purpose. A large proportion of rice in the mash-tun gives the beer a watery taste, unless more body is given by the addition of sugar or some other form of saccharine material. It is usual, therefore, to adjust the quantities of malt substitutes employed so that the deficiencies of one shall be counterbalanced by the excesses of another. The amount of malt grain used in the mash-tun may be further reduced by the addition of malt extract, which is supplied to brewers in large quantity for the purpose; this contains the diastase necessary for converting the starchy material, as well as proteid and sugars for use at the later stage.

The next process, that of boiling with hops, does not lend itself to the use of substitutes on the same liberal scale as does the mashing. The tannin which is extracted from the hops by boiling assists in precipitating the coagulable proteid, and tannic acid or other materials containing tannin are used to a small extent. The bitterness which hops impart can of course be obtained in other ways, and quassia is the substitute principally in favour for this purpose; the result, however, is not a satisfactory imitation, as the bitter taste on drinking hopped beer is evanescent, while quassia leaves a more enduring bitterness in the mouth. The only "hop substitutes" which will give the characteristic hop flavour are preparations of the hop itself, which are sometimes used; while the antiseptic and preservative property of hops may be replaced by the use of substances added as preservatives, which, however, are introduced at a later stage.

After the boiling, the wort is cooled and yeast added; as already stated, yeast can decompose other sugars besides the maltose formed in the mash-tub, and the addition of one or more kinds of sugar is very usual. A further quantity is also commonly added after the chief fermentation is over; most of this remains in the beer, but a small quantity is decomposed in the secondary fermentation in the cask. The sugar most employed is invert sugar, usually produced by the action of sulphuric acid on cane sugar; glucose (starch-glucose or starch-sugar), produced by the action of sulphuric acid on starch, is also largely employed; cane sugar, dextrin maltose (made by acting on starch with acid, but not carrying the action so far as the production of glucose), and caramelized malt extract are also used. The sugar may or may not be added to the mash-tun, but it is almost always added before boiling with hops, so that other organisms shall be destroyed and the yeast allowed a free field.

The colour of beer depends primarily on the materials employed in the mash-tun. Various kinds of malt, known as amber malt, chocolate malt, crystal malt, black malt, etc., are prepared by kilning at higher temperatures or for longer times than those employed when diastase is required, or by subsequently roasting the malt; the use of a suitable proportion of one or other of these in the mash-tun gives the desired colour. But considerations of cheapness lead to roasted barley and maize being substituted, or to the still simpler method of adding sufficient caramel (burnt sugar) to give the required depth of colour.

The addition of some antiseptic to beer is very usual; a sulphite or bisulphite of one of the alkali metals or of lime is most frequently employed, while salicylic acid (about $\frac{1}{2}$ oz. to the barrel of 36 gallons) is also used, and some other substances in small quantity. When too much acidity (principally lactic and acetic acids) has developed in the beer during the making or storing, it is neutralized by the addition of carbonate or bicarbonate of an alkali; these are commonly supplied to the brewer under proprietary names. Before bottling, clarification of beer is usually effected by the addition of an acid solution of isinglass or some other gelatine preparation or similar substance. This combines with a part of the tannin in solution, and the precipitate which is produced carries down with it yeast cells, traces of proteid, and other suspended matter.

The chief instance in which a deleterious substance has been found widely distributed in beer is that in which a few years ago arsenic, present in certain beer, produced a number of cases of arsenical poisoning manifested chiefly by neuritis; in this instance the arsenic had been intro-

duced in glucose, one of the malt substitutes employed. The thorough search for arsenic in all brewing materials resulted, however, in showing that malt itself was very commonly contaminated with arsenic from the coke fires employed in kilning, and could be the means of introducing quite appreciable quantities of arsenic into beer. The lesson to be drawn from this is, of course, that all the materials used in producing beer (and other articles of food and drink), whether "natural" or of the nature of substitutes, ought to be thoroughly examined by persons competent to judge them, before being used. The present freedom of the brewer to use practically any materials he pleases, subject to their being innocuous, by immensely increasing the field from which he can draw, certainly increases the risk of deleterious substances being introduced, as well as of the product being only a skilful imitation of what is really demanded; and although the restriction of brewers to the materials used in ancient times does not appear to be called for, and, as shown by the arsenical contamination of malt, would not of itself be an adequate guarantee of the quality of the product, it is certain that the prevailing practice of making beer from such a very wide variety of materials demands the utmost watchfulness on the part of the authorities.

LITERARY NOTES.

MESSRS. WILLIAM HODGE AND COMPANY, Edinburgh and Glasgow, are about to publish a new volume of their *Series of Notable Scottish Trials*. It deals with the William Douglas case, an eighteenth century trial which excited the greatest interest throughout the country. Readers of Boswell will remember that there are several references to the case in his *Life of Johnson*.

The same publishers have in the press a small book by the Rev. Father Power, S.J., of Edinburgh, entitled *The Alcohol Case: the Summing Up. A Medical, Legal, and Historical Sketch*. The author is a member of the London Society for the Study of Inebriety, and a well-known lecturer on intemperance.

We have received a descriptive catalogue of the medical and surgical works published by Messrs. W. B. Saunders Company. It is revised up to January, 1909. The specimen illustrations which accompany the titles of many of the books are admirably executed.

Among the many stories told of Rabelais some are undoubtedly apocryphal. The following is one of the authenticity of which we can give no proof, but which we could wish to be true. The Chancellor Duprat being for some reason annoyed with the Medical Faculty of the University of Montpellier, curtailed it of its privileges. The Faculty chose Rabelais to plead its cause. The difficulty was to get an audience with the irate Chancellor. Rabelais succeeded by stratagem where he would probably have failed by going about the business in a straightforward manner. Disguising himself in a green gown and a long grey beard, he walked slowly up and down before the Chancellor's house. His strange appearance naturally attracted attention, and among others who came to stare at him was the Chancellor's porter. Rabelais spoke to this functionary in Latin. On his answering in what little dog Latin he could produce to meet the situation, Rabelais replied in Greek. This brought a Greek scholar on the scene, to whom Rabelais spoke Hebrew. By this time the Chancellery was in commotion, and Duprat sent for the strange man who had exhausted the linguistic resources of his staff. He was so much amused by Rabelais's trick, and so interested by his conversation, that he forthwith granted him all he asked for.

The second number of the *Journal of the Incorporated Society for the Destruction of Vermin* contains an article on vermin by the editor, Mr. W. R. Boelter. He says that a study of the writings of ancient and mediaeval authors will yield thousands of recipes for the destruction of parasites. The searcher will also find how parasites themselves have in their turn been used in an endeavour to cure numerous ailments, a proceeding which, Mr. Boelter says, has in many cases been vindicated by the researches of modern chemistry. He goes on to point out that man in his fight against vermin has been singularly unsuccessful. One reason for this failure is man's inability to agree about what is and is not vermin. The

equivalent of vermin in the ancient languages and in mediaeval books was applied to everything of a noxious or loathsome nature. In the Ebers papyrus twelve species of *vermes* are mentioned. In the Middle Ages Meigenberg counted among *vermes* the bee, the spider, the toad, the silkworm, the gnat, the flea, the louse, the wasp, the caterpillar, and larvae of different species. This writer's zoology reminds us of that of the railway porter who, having to deal with a tortoise, delivered himself as follows: "Cats is dogs, and rabbits is dogs, but this 'ere's a hinsect, and must be paid for." Vermin in German is *ungeziefer*, that which is not fit to serve as an offering to the Deity. Hence vermin was thought to be associated with the devil, and played a large part in witchcraft. About the end of the seventeenth century two books on the destruction of vermin were published in Germany, one by a physician named Hobberg, the other by Abraham Friedrich Krafft. Mr. Boelter thinks that Krafft's book led to the formation of a society for the total extermination of all vermin. Willis, whose name is enshrined in the arterial circle at the base of the brain, discussed in a treatise entitled *De Anima Brutorum* the question whether vermin have souls, concluding affirmatively, and adding that, "although vermin are mostly of a cold nature and essence, their souls are, like those of the warmest and most perfect animal, heated and fiery, and consist of a sulphurous essence."

Writing in the *Boston Medical and Surgical Journal*, Dr. Charles G. Cumston says that for a long time he has searched in the writings of the ancient physicians with the hope of finding some description of appendicitis. Both Hippocrates and Galen are silent on the question. Celsus, however, appears to have been familiar with appendicitis, because, in speaking of colitis, he says:

The disease of the large intestine is principally situated in the cecal portion. Considerable swelling and violent pain are observed, particularly on the right.

He advises the application of hot, dry fomentations. Of the writers during the period of the Decadence, Dr. Cumston has consulted Aetius, Oribasius, Paul of Aegina, and Alexander of Tralles. In the *Tetrabiblion* of Aetius (cap. xlii, lib. ix) the following remarks are to be found, which, in Dr. Cumston's opinion, undoubtedly refer to suppurating appendicitis:

Occasionally abscess of the intestine occurs, whose rupture gives rise to purulent stools.

After stating that this condition is often erroneously diagnosed as dysentery, he goes on to say:

In abscess of the intestine there is a localized pulsating pain. There are no colics such as are observed as forerunners of an attack of dysentery. When the abscess has matured the temperature goes up and is more marked in the evening. When the stool has collected, the morbid phenomena diminish and the pain becomes less acute, only to recur when rupture of the abscess takes place. Sometimes there is obstinate constipation. Nothing like this is encountered in dysentery.

He advises the use of linseed-meal poultices to which is added some astringent, such as blackberry wine, etc. According to Dr. Cumston appendicitis was apparently unknown to Soranus of Ephesus, because Coelius Auresianus, whose writings are merely an abbreviated translation of the works of the former, gives no description of the disease.

Dr. W. G. Atchison Robertson, of Edinburgh, writes:

That the teaching of such authorities as Valsalva, van Swieten, Morgagni, and others (who believed in the infectious nature of phthisis) had been carried into practice in certain countries, is evident from the following quotations from John Howard's work on *The State of the Prisons in England and Wales, with an Account of some Foreign Prisons and Hospitals*, third edition, 1784.

Speaking of the Italian prisons, he says that at Civitavecchia "here is a spacious hospital on shore for the slaves. None were in irons. All was clean. In the centre of the great room in this infirmary was an altar for public worship. A particular room was appropriated for such as had cutaneous disorders, and another for consumptive patients. In this country the physicians are persuaded that the *consumption* is a contagious disorder. Patients afflicted with it in hospitals have a separate ward. The same precautions are used to prevent infection as in the plague. When this disorder has been in private houses the furniture is destroyed, and the rooms are scraped and fumigated, before they are again inhabited" (page 116).

He alludes to the same belief when describing the *Real Hospital General* in Madrid. "Here are likewise rooms (carefully separated for measles, for dropsical, and for consumptive patients. The contagion of consumption is supposed to infect

not only the clothes, bedding, and furniture of rooms, but also the walls and ceiling. Danger has been apprehended even from the horses of consumptive patients; and for this reason it was thought necessary, in an instance that was mentioned to me, to kill the horse of an officer who had died of this distemper" (page 158).

The doctrine of the infectivity of phthisis is much older than any of the authors mentioned by Dr. Aitchison Robertson. It was held by Aristotle and later by Galen. In the fifteenth century it was taught by Ballonius or Bailion of Paris, in the sixteenth by Cesalpinus, and by Paolo Zacchia and Nicholas Chesneau in the seventeenth, to mention only a few of the old writers who have dealt with the matter. Most stringent regulation as to the disinfection of the rooms in which consumptives had died in the eighteenth century were enacted in Spain and in Italy, and were in force in both countries till the nineteenth century was well advanced. That phthisis is communicable is an old belief, which was only partly given up in accordance with what was supposed to be more scientific medical teaching.

Medical News.

MR. ALFRED E. WILNOT, M.R.C.S.E., L.R.C.P.Lond., Burnham House, Burnham, Bucks, has been made a Justice of the Peace for the county of Buckinghamshire.

THE Lord Mayor of London and the Lady Mayoress will hold a reception at the Mansion House of the delegates and members of the International Congress of Nurses on the afternoon of the opening day, July 20th.

SIR JOHN CRAGGS having placed at the disposal of the London School of Tropical Medicine a fund to encourage investigations into the various causes of tropical disease, grants from this fund have been awarded to R. Howard, M.D., of the Universities Mission to Central Africa, and to B. M. Wilson, M.B., Ch.B., of Fiji.

THE members of the Glasgow University Club, London, have presented to Dr. C. O. Hawthorne a study table and microscope in recognition of his services as honorary secretary of the club during the past seven years. The presentation was made by Dr. Cunningham Grant on behalf of the subscribers, many of whom were present. The company was entertained by Dr. and Mrs. P. H. Abercrombie, who kindly placed their house at the disposal of the committee.

WE are asked to state that hospitals in the county of London or within nine miles of Charing Cross desiring to participate in the grants made by King Edward's Hospital Fund for London for the year 1909 must make application before March 24th to the Honorary Secretaries, 7, Walbrook, E.C. Applications will also be considered from convalescent homes and sanatoriums for consumption situated within the above boundaries or which, being situated outside, take a large proportion of patients from London.

A MEMORANDUM by the Medical Officer of the Local Government Board in England, on administrative measures against tuberculosis, has been issued, and can be obtained, price 2d., through any bookseller. It supplements from a medical standpoint the information contained in a circular letter issued by the Local Government Board to all sanitary authorities and boards of guardians sent out along with the Public Health (Tuberculosis), 1908, Regulations.

THE Departmental Committee appointed by the Lord President of the Council to consider the working of the Midwives Act held its sixth meeting on Wednesday, March 10th, at the Privy Council Office, Mr. Almeric FitzRoy presiding. The following witnesses attended and gave evidence: Sir George Foddham, Treasurer of the Central Midwives Board and representative of the County Councils Association; Dr. A. Robinson, Medical Officer of Health for the County Borough of Rotherham; and Mrs. Heywood Johnstone, President of the Rural Midwives' Association.

THE London County Council has issued an order renewing for a further period of twelve months from March 13th the regulation requiring the notification of cases of cerebro-spinal fever (epidemic cerebro-spinal meningitis). On the advice of a committee appointed by the president of the Royal College of Physicians the council has decided that for notification purposes the disease at present known as posterior basal meningitis shall be included in the term cerebro-spinal fever, but that the term is not to be interpreted as including cases of meningitis due to tuberculosis, middle-ear disease, or injury.

As already announced in the JOURNAL of December 26th, 1908, a convention which will include all branches of

medical electricity will be held in London from July 5th to 9th, 1909. The President is Dr. Lewis Jones; the Vice-President, Mr. Deane Butcher, President of the Roentgen Society; and the Honorary Secretary and Treasurer, Dr. Reginald Morton. The inaugural meeting, the general meetings, the demonstrations, and the exhibition will be held at University College, Gower Street. The exhibition will include all classes of electrical and physical apparatus for medical treatment. It will be held contemporaneously with the convention. Delegates will be present from America and the Continent, and representatives of the various foreign Governments will be invited to take part in a discussion as to the best means of providing apparatus and training for the army and navy. The papers and debates will be in English. Papers in French and German will be accepted provided a summary in English is sent. All papers will be reported either in *extenso* or in abstract in the *Archives of the Roentgen Ray*. The discussion on Roentgen and radium therapeutics will be under the charge of Dr. J. H. Sequeira, and medical men desiring to read papers or to take part in the discussion are requested to communicate with him at the London Hospital. The time required for the delivery of each paper should not exceed fifteen minutes. All other communications relative to the congress should be addressed to Mr. Ernest Schofield, Organizing Secretary of the Convention, 11, Chandos Street, Cavendish Square, London, W.

IN a paper on preparations of lactic-acid bacilli, read recently before the Chemists' Assistants' Association, Mr. W. H. Martindale, Ph.D., brought forward some interesting facts in regard to the production of sour milk and the preparations obtainable for the purpose. It has been stated that there are about 150 lactic-acid-producing organisms. The three bacteria which it appears most desirable to employ together for the production of sour milk for consumption are *Bacterium caucasium* (the Bulgarian bacillus), *B. gūntheri* (also known as *Bacillus acidi paralactici*), and *B. hūppe* (also known as *Bacillus acidi lactici*). Six preparations now on the market for this purpose were examined, after cultivating for ten and for twenty-four hours. All were found to contain *B. caucasium* and *B. hūppe*, but *B. gūntheri* was found in only one; one of them showed other organisms, and a second had developed cocci after twenty-four hours. Experiments were made on incubating milk after the addition of lactic or acetic acid, without bacteria; as was to be expected, if the milk was efficiently sterilized before beginning the incubation, no additional acid was produced, but when sterilization was omitted substantial amounts of acid were formed; in the milk so treated *B. hūppe* was identified, but no *B. caucasium*. A few experiments on the extent to which the casein was rendered soluble during the action of the lactic acid organisms pointed to such a change being effected to only a slight extent, but the matter was not conclusively dealt with; the proportion of the phosphate dissolved in the whey was found to be increased. Soured milk supplied by some dairy companies was examined in regard to the organisms present: *B. hūppe* was the prevalent form, *B. caucasium* being present in smaller quantity, and *B. gūntheri* also in half the samples examined.

CHELSEA CLINICAL SOCIETY.—The annual dinner of the Chelsea Clinical Society took place on March 4th at the Gaiety Restaurant, and was well attended. The chair was taken by Mr. A. F. Penny, the President of the society, who, in proposing the toast of the evening, described how the society had begun from a discussion held between Dr. Austin Cooper and himself twelve years ago. They then started the society at the old Chelsea Dispensary, with Dr. Foster Palmer as their first president. Societies like theirs, Mr. Penny added, contributed not only towards uniting the medical profession by the social influence of their meetings, but also aided the scientific advancement of medicine. Dr. T. Wright Parkinson, in replying, expressed the hope that medical men in Chelsea who were not members would attend their meetings and learn that it was not a mutual admiration society, but a society doing useful work. The Rev. Dr. Colisson, who also spoke, had a most enthusiastic reception, which was renewed on his singing, after repeated calls, "The Mountains of Moine." The toast of "The Visitors and Kindred Societies," proposed by Dr. Sevmour Taylor, was acknowledged by Colonel T. H. Hendley, the President of the West London Medico-Chirurgical Society. Dr. J. Blumfield, in a witty speech, then gave the toast of "The President and Officers of the Society." It was duly responded to by Mr. Penny, who expressed the obligations of those present to Dr. Collis Hallowes for his successful arrangements for the dinner.

British Medical Journal.

SATURDAY, MARCH 13th, 1909.

THE MARCHING SOLDIER.

It is astonishing that it should be necessary for a committee of the Advisory Board of the Army Medical Services to report in the year of grace 1908! "that it be an instruction to officers commanding that the order shall be given to men on the march in warm weather to open the jacket and shirt"; "that inefficiency and injury to health can be greatly lessened or abolished by allowing free evaporation of sweat to take place through the exposure of shirt and skin"; "that each young soldier should perform at least one march a week," and that "the load carried and the distance traversed in these marches should be progressively graduated."

The power to strike a decisive blow, the fate of a war, depend more than anything on mobility—on the marching power of the soldier—and this, as every schoolboy or girl knows who has been through a primer of physiology, depends on the training of heart and muscles, on the adequate supply of food and drink, on suitable clothing, and the proper provision of periods of rest. It is Gilbertian comedy to read the list of dignified names—Sir Alfred Keogh and Sir T. Gallwey, Sir Frederick Treves, and half a dozen colonels and lieutenant-colonels, with Drs. John Haldane and Pembrey as the *dei ex machina* behind this great reform—which allows Tommy Atkins to unbutton his coat when he is hot. The civilian is still to be left the advantage of being able to throw his off and carry it, rolled up, by a strap on a hot day's walk. The committee dare not go as far as that—yet. Let the poor sweating private be content with the buttons undone in front and his shirt open at the neck. Comic as it may be, there is tragedy behind—years of tragedy, of men commanded by officers who knew nothing of the elements of science or the simplest laws of health, officers who have handled the most perfect of machines, the living body of man, and have regarded it often from little other point of view than that of making it look smart and keep time like a wooden puppet dancing on a string. "All light infantry and rifles march with a quick short step; it is doubtful," says the committee, "if this is economical in a physiological sense" (or in boot leather), "and it is certain that it is opposed to efficient co-operation with men who have been trained to march at the ordinary pace." How many have been made to suffer and how many have been killed in times of peace by marches and reviews on hot days with stiff tunics buttoned up and the heavy loads of full marching order! "Free exposure of the shirt saved the body a loss of above a pint of water during a march of seven miles in two hours." "The loss of moisture produces a thirst which must be and is satisfied, and unfortunately not always from the most suitable source." "On a hot summer's day a march produced on soldiers in drill order as great an effect as a similar march in full marching order with 100 rounds of

"ammunition on a cool winter's day." "By frequent practice a man may develop his capacity to carry loads, but he can only raise to a limited extent his power of resisting the effects of a hot, moist, and stagnant air." "On a hot day, 79° dry and 67° wet bulb, five men during a march of seven miles in drill order lost by evaporation an average of over 3 pints of water."

The committee have found that the speed with which the pulse frequency falls to normal during a halt is the most valuable guide to the condition of the man. Training makes the return of the pulse to normal frequency very rapid. In the untrained and over-exhausted the pulse keeps frequent for a long time. We may note here that the recent work of Mr. Leonard Hill and Mr. Martin Flack has shown that the inhalation of oxygen brings down the pulse frequency, and sends up the blood pressure in the exhausted athlete; training consists in the development of cardiac power, so that the body obtains an ample supply of oxygen. The committee put forward some evidence that smoking lessens the efficiency, and recommend "that smoking in the ranks should be strongly discouraged," and there is reason to believe that cigarette smoking keeps the condition of the heart and vitality of the man below par. The few observations made on the drinking of water or beer on the march show no clear result; beer does not appear to be so great an offender as the cigarette; the latter escapes at present with comparatively little condemnation from the reformers. The committee, in their observations and recommendations, confirm the results obtained a decade ago in Germany by Zuntz and Schumburg, who in 1900 published a most valuable and suggestive monograph on the physiology of marching. They made very careful observations on young medical recruits, and determined the most suitable load, the distribution of the load so as not to interfere with the body movements, the length of march suitable for different conditions of the atmosphere, the effect of training, of a sore heel, etc., on the efficiency of the body as a marching machine, the adequacy of the rations, and so on. We may thank Heaven that the War Minister has a brother who is a distinguished and sound physiologist, and that he himself believes in the application of science to the affairs of daily life, and in the attainment of efficiency by science.

MYTHOMANIA.

WE are all familiar with the liar of the type of the Rev. Charles Honeyman in *The Newcomes* to whom Fred Bayham said: "Excuse the frankness of an early friend, but it is my belief that you would rather lie than not." Sometimes the tendency is constitutional as in the family of a famous historian—himself somewhat remarkable for inaccuracy—of whose daughters it was said that one lied because she could not help it, another because she thought it was right, and a third because she thought it was wrong! As lying is an ugly word, we are thankful to the inventor of the euphemism "mythomania." In the subjects of this disease lying may be unconscious. Charity makes us willing to believe that it is often this form which afflicts the people who make such wonderful statements about vivisection, vaccination, cancer cures, and the therapeutic virtues of certain methods of treatment—for we are sorry to say the mythomaniac is by no means unknown in the medical profession. The disease has its source partly in want

¹ Second Report on the Physiological Effects of Marching, by the Committee on the Physiological Effects of Training, Clothing, and of the Food of the Soldier.

of training in regard to accuracy of statement, for most children lie instinctively in self-defence, or out of vanity, just as those subject to authority lie to escape punishment or reprimand, and as artists lie *pour épater le bourgeois*. Partly it has its source in an overvivid imagination, partly in that "wish to believe" which is said to be the foundation of faith—the kind of faith that, in the too candid definition of the schoolboy, is the faculty whereby we are enabled to believe that which we know not to be true. This is probably the explanation of the strange disregard of truth which is often found in persons otherwise of the highest moral character. But it is not with the unconscious or half-conscious liar—or shall we say economist of the truth?—that we are here concerned, but with the conscious mythomaniac. This form of the disease the doctor has probably even larger opportunities of observing than the lawyer, although it was cynically said by Lord Justice Bowen—or some other judicial authority, for there are several claimants to the honour of the *obiter dictum*—that "truth will out, even in an affidavit." After all, for most people some sanctity hedges about an oath, and there is the possible penalty for perjury also to be considered. It would seem that, except in a few cases in which disgrace and perhaps something worse may attach to the confession of the cause of disease, a patient has no motive for lying to his doctor. That patients do lie, nevertheless, is within the knowledge of every one of us; but few perhaps realize the extent to which they lie.

The doctor who told Mr. Rudyard Kipling that "all patients were phenomenal liars where their 'own symptoms were concerned'" was evidently a man of wisdom ripened by long experience. Such a one, too, is Dr. Quintard, who not long ago gave the Société de Médecine d'Angers the benefit of what Iago calls his "own gained knowledge" of the subject. He makes all due allowance for shame, the dread of operation, and the loss of mental balance due to suffering. It is somewhat strange that he does not mention the *suppressio veri* practised by many who do not wish to have a secret fear confirmed; nor does he mention the lying which is one of the symptoms of hysteria or of the abuse of narcotics. Dr. Quintard, in fact, deals with the people who come to the doctor with the deliberate intent to deceive.

There is the gentleman who, with a breath reeking of alcohol, complains of cramps of the stomach, and swears that he drinks nothing but a mineral water even at meals. There is the lady who wishes to be sent to a fashionable health resort against the wish of her husband. There is the official who asks for a certificate that will get him a billet in the sweet South, which he covets on account of an asthma which has the awkward peculiarity of not manifesting itself by any outward and visible symptoms. There is the lady with a decayed molar who prefers that her suffering should be dignified by the name of neuralgia. There is the lady who wishes for a certificate that will give her a free passage to Lourdes to be cured of an appendicitis on the left side. There is the veteran with sciatica, which he attributes to a fragment of a projectile which has remained embedded in his gluteal region—not, surely, a noble part for a soldier to be wounded in—since he was hurt at Sedan, but who declines to allow the foreign body to be revealed by the x rays. There is the too common case of a widow who says she has already undergone an operation for fibroma, and pleads for another, but who is delivered from her

tumour in due course by a practitioner of the obstetric art. There are many more—but these are examples of the more ordinary varieties of conscious mythomania, and they are so common that many doctors in large practice are tempted to say in their haste that all patients are liars. They lie to excite sympathy, from the wish to pose as remarkable cases, to escape work, to impose on charitable persons, or for the mere pleasure of deceiving the doctors. We mention these instances not as exhausting the art of the mythomaniac, but for the edification of the young practitioner who may not have learned that for ways that are dark and for tricks that are vain the Heathen Chinee is a model of truth and honesty compared with many patients. It should be needless to insist that reliance should never be placed on the statements of a patient about another doctor, or about the opinions attributed to him, but, as we have too much reason to know, half the quarrels of professional life are due to this cause. As far as possible a doctor should form his opinion on things which he can see, or facts which he can discover by physical examination. Pediculosis may be the source of irritation on the skin of a duke's son as well as on that of a cook's son, and the most icy chastity does not exclude the possibility of syphilis.

INTERNATIONAL MEDICAL ETHICS.

THE subject of medical ethics has claimed a great deal of time and attention from the British Medical Association, and at the present moment the Central Ethical Committee has in preparation an index of ethical cases which may serve as the basis for a special ethical code. Many of the points raised are knotty ones, and there has been no little difficulty in arriving at a fair and equitable solution of some of the questions. It may, however, be stated that medical ethics are in a more advanced state in this country than in any other. We do not wish to imply by this that the German or French idea of what is ethical and what is unethical, because it may differ from ours, is either lax or unsound.

Ethics in medical conduct must necessarily depend on the members of the profession to whom the rules apply, and the views which they take as to the degree of protection upon which the individual members have a right to rely. The rules must also be influenced by the amount of protection which the law is willing to extend to regular medical practice; and it is probable that the chief reason why ethics in medicine are governed by stricter rules in this than in other countries is to be found in the fact that in no other country does the law of the land do less for the medical profession.

In medical ethics, however, there must be a certain number of fundamental points common to the conditions existing in all countries, and although these points have not yet been tabulated and formed into an ethical code, there is no doubt that such a code could be drawn up. About eighteen months ago, Professor Boas, of Berlin,¹ made a number of suggestions which he considered might serve as a basis for an international code. He has recently returned to the subject,² with special reference to an unfortunate difference between two medical practitioners in Pontresina and a doctor in Berlin. We do not propose to discuss this particular case, since according to our practice no judgement can be passed unless both

¹ *Berliner Aerztekorrespondenz*, 1907, No. 37.

² *Berl. klin. Wuch.*, 1908, No. 52.

sides have been heard and examined in such a way as to remove all doubt as to facts. But we wish to call attention to Professor Boas's suggestion, which seems to us wise and practicable. It is that at the forthcoming International Medical Congress, which is to be held at Buda-Pesth, the question of international medical ethics should be discussed in one of the chief sessions. It might not be possible to come to any definite conclusions which could govern international medical ethics, but, after various views had been brought forward, it would be competent for the meeting to elect a committee representing all European countries to consider the subject, to draw up a scheme or code, and to submit the same to the leading medical societies or associations of the various countries, which could either accept the code, or suggest amendments, or refuse it. The Committee could continue to act until a code could be produced which would prove acceptable to all countries, and after such approval had been obtained the code would be held to regulate the professional relations of foreign medical practitioners with one another. Professor Boas has chosen an opportune moment, and if his suggestion is taken up and developed along the lines indicated, thanks will not only be due to him, but will be freely given.

THE COMING ANNUAL MEETING AT BELFAST.

PREPARATIONS for the meeting of the Association in Belfast in July next are being vigorously carried on there. Nine subcommittees are at work in various departments, and every effort is being made to prepare for a large number of visitors from across the channel. The Lord Mayor has signified his intention of inviting the members of the Association to an evening reception in the fine new City Hall on Wednesday, July 28th. Several garden parties are being arranged, and it is hoped that those members who care for sailing may have an opportunity of indulging in that pastime on the waters of Belfast Lough, while enjoying the hospitality of one of the yacht clubs. Golfing members will be specially well cared for, as a large proportion of the local members of the profession are golfers, and some of them very successful ones. A special competition, of which particulars will shortly be published, is to be held at Newcastle, co. Down, which boasts of the most sporting links in Ireland.

THE REGISTRATION OF NURSES.

THE dissatisfaction felt by leading members of the profession in Ireland at the supposed exclusion of that part of the United Kingdom from the scope of the bill for the registration of nurses found expression at the annual meeting of the Leinster Branch held in Dublin on February 13th. As a matter of fact, however, the bill in its latest form does apply to Ireland (see BRITISH MEDICAL JOURNAL, February 13th, p. 419). Nevertheless, in accordance with the request of the Honorary Secretary of the Branch, we give the full text of the resolutions carried on the occasion, which he has been good enough to send us since the date of the first report:—Dr. Craig proposed, Sir W. Smyly seconded, and it was unanimously resolved: "That we do not approve of any bill dealing with the registration of nurses which does not contain clauses providing: (a) That the bill apply to Ireland; and (b) that the registration of a nurse confers no authority to practise any department of medicine." Sir W. Smyly proposed, Dr. Furlong seconded, and it was unanimously resolved: "That we think in future at least three years' hospital training should be

"insisted on in order to qualify a nurse for registration." Dr. Craig proposed, Dr. Furlong seconded, and it was resolved unanimously: "That in each country affected by the Act a register of hospitals should be kept by a Branch Council, who should be also empowered to examine and register nurses, uniformity of curriculum and of examination in the various countries being secured by the presence, when advisable, of inspectors or visitors. The register should be a general one, applicable to all parts of the United Kingdom." It may be added that another matter dealt with in somewhat summary fashion in the first report supplied to us was the Referendum and Charter. We now give the terms of the resolution passed, as officially reported to us by the Honorary Secretary. He states that correspondence with the South-Western Branch was read, and the following resolution was, on the motion of Dr. Kidd, unanimously adopted: "That, in the opinion of the Leinster Branch of the British Medical Association, it is necessary for the safe government of the Association that the Referendum be taken by a letter to every member of the Association, and on the requisition of half the Council." The Branch Secretary was instructed to forward a copy of the resolution to each of the Divisions in the Branch.

THE PRESS AND MEDICAL MATTERS.

A CORRESPONDENT of the *Times* takes it much amiss that we should have been made "the channel of information to the public and the medical profession upon a subject of great importance to both." The subject referred to is the Radium Institute lately founded on the personal initiative of His Majesty the King, as to the objects of which we obtained an official statement which we thought it our duty to circulate to the press. The writer in the *Times* hides his amiable personality under the pseudonym "F.R.C.S.," but we may say of his identity, what Sir Thomas Browne said of the name Achilles assumed when he hid himself among the women, that it is not beyond all conjecture. We confess we do not see the inconvenience either to the public or to the medical profession of which he complains. On the contrary, we hold strongly that a medical journal is the proper channel of information on medical matters. The information was obtained by us in response to several questions on the subject of the Radium Institute which had been addressed to us. It may be remembered that we alone furnished accurate information as to the institution at a time when most of the London daily papers allowed themselves to be misled by an inaccurate announcement. We do not seek to penetrate the motives of those who supplied that information, nor do we think it necessary to say anything as to the facility with which the newspapers suffered themselves to be beguiled into announcing to the public, with a journalistic *fanfare* of the most brassy quality, a communication which might have been easily recognized as coming from some doubtful source of inspiration. However "inconvenient," therefore, it may possibly be to individuals, we think that it is a very distinct convenience to the general public to have information on medical matters conveyed through a channel whose character carries with it a guarantee of the genuineness of the information with which it is its province to deal. We go so far as to say that the medical press should be the sole channel for the conveyance of information on such matters. As we have often pointed out, the mischief done by the publication of incorrect reports of scientific discoveries and imaginary marvels of surgery is beyond all computation.

SPIRITUAL HEALING.

SPIRITUAL healing is still receiving a considerable amount of attention. A meeting of the Church and Medical Union was held at Church House, Dean's Yard, Westminster, on March 8th, when Dr. Lullum Wood Bathurst read a paper in which, according to a brief report published in the *Times*, he seems to have "dealt faithfully" with those among the clergy who dabble in the unqualified practice of medicine, either in their own persons or by supporting persons who, whatever may be their spiritual gifts, have no medical training. He quoted from the *Church Times* significant statements to the effect that the movement within the Church had grown silently but surely, and that the records of its achievements were not known to the world, but were known to those who had a right to know. We may be allowed to remark on this that those who have a right to know are the public, and that the promoters of the movement are neither philanthropic nor wise in hiding their light under a bushel. Dr. Bathurst pointed out that, so far from any desire being shown on the part of the Church to co-operate with the medical profession in this matter, there was ample evidence of individual clergymen in responsible and even exalted positions actively supporting unqualified persons who, from the medical point of view, could only be looked upon as quacks and charlatans. One effect of the silent action on the part of the Church, referred to by the *Church Times*, was that the medical man was met with the difficulty, or the impossibility, of knowing what the Church proposed to do, the treatment its members intended to carry out, and the methods to be adopted. Still more vague were the qualifications of the "carefully selected persons" so often spoken of, to whose treatment patients were to be subjected. In conclusion, Dr. Bathurst suggested an inquiry and authoritative information from the Church on certain points, to enable an understanding to be reached between it and the medical profession. But we do not think the profession will be disposed to meet the Church unless she bates her pretension to the gift of healing the body. There is no doubt that in certain cases the clergyman can help the doctor, but he cannot, without danger to the community, be allowed to take purely medical functions upon himself. As showing the widespread interest felt in the Emmanuel Movement, it may be added that Dr. Henry Rutgers Marshall, of New York, has dealt with psychotherapeutics in the January number of the *Hibbert Journal*, and that "the healing power" forms the subject of an essay by M. A. Stobart in the *Fortnightly Review* for February, while Dr. A. T. Schofield discusses spiritual healing in the current number of the *Contemporary Review*. There is nothing, however, particularly new or illuminating in any of these articles. In an article published in the *North American Review* for February, Dr. Allan McLane Hamilton calls attention to a point which is generally forgotten or overlooked by the clergymen who are so anxious to co-operate with us in the healing of the sick. "In all this agitation," he says, "it would almost seem as if the intelligent physician had never made any use of psychotherapy, but that he was a mechanical giver of drugs and took little or no interest in his patients." He goes on to say, what has so often been said in this JOURNAL, that "if the new critics of the medical profession, who have been so active of late, would take the trouble to investigate, they would find among the great and successful men of all times and of to-day, that the human side is very strongly developed and that their patients are studied from every point of view and treated accordingly." We would add that the intelli-

gent application of the physician's knowledge of the influence of the body on the mind is a necessary condition of success in the difficult art of dealing with patients and reinforcing the curative power of Nature, or what comes to the same thing, enabling sufferers to work out their own deliverance from the thralldom of functional disease. All really great physicians have used this force, sometimes it may be unconsciously, but often with deliberate intent. It is the power of influencing the mind of the patient, or in other words, of exciting confidence in his "gift of healing" that makes what is called "personal magnetism."

FAILURE OF ANTIVACCINATION CAMPAIGN IN THE STATES.

THE petition for the abolition of compulsory vaccination in Massachusetts, backed by the State Antivaccination League, has failed to influence the Legislature, and "leave to withdraw" was reported by the Public Health Committee at a meeting of the Senate a few weeks ago. Last year Mr. Bonner, who was then the militant attaché of the Antivaccination League in this country, but whose services had to be discontinued for want of funds, entered on an American campaign. We have already recorded a glaring instance of misrepresentation by which his advent in Boston was heralded in the press. That misrepresentation was duly corrected in the Boston papers by correspondence from England. From a correspondent who has forwarded us press excerpts and particulars of the hearing before the committee, we gather that Senator Parker, as chairman, had a trying part to perform in an attempt to maintain order. The antivaccinators were allowed to consume much time, but instead of being grateful for this, they gave vent to their emotions, uttering groans or sneering laughter, at the statements by eminent physicians who came to oppose the petitions. Senator Parker attempted to treat them with courtesy, but it finally reached a point where the chairman had to threaten to dismiss the hearing. The correspondent adds: "Six of our most eminent physicians spoke from personal experience, and, as we say here, they put it all over the anti-vaccinationists." Mr. Bonner is stated to have announced to the committee his intention of becoming a citizen of the States as soon as the laws could permit. The provaccinists on the other side of the Atlantic are fully alert in watching the vagaries of this doughty agitator, and are ready to cope with his "platform facts." There is much boasting of what Mr. Bonner has done in this country in spite of the candid confession, officially made here by the Antivaccination League, of the almost complete failure of "our objects." The wild statements and grotesque theories propounded before the Massachusetts Senate Committee were such that the hearing is stated to have developed into a laughable affair at times. If the members of the Senate were familiar with the state of affairs in the House of Commons, they would know that whenever the subject of vaccination is mentioned by the leading antivaccination member it is a signal for peals of derisive laughter, and the complaint of the rabid antivaccinators in this country is that no responsible persons or authorities treat their remarks seriously.

RADIO-THORIUM.

PROFESSOR SODDY has contributed to *Nature* an account of radio-thorium. This body he assumes to be the same as that described recently in a telegram to the *Daily Telegraph*, on the authority of Dr. Bailey of Chicago, under the name of radio-thor or thor-rad X, and characterized as a very marvellous and remarkably efficient substitute for radium. After eliminating American hyperbole, it would appear that Dr. Bailey

has found that the body called radio-thorium exists in pitchblende from Colorado. The claims of Dr. Bailey to have made a new discovery are on the same footing as those of a miner who claims to have discovered a gold field. The results may be of great value, but it is impossible on this account to claim any scientific advance. Even the idea of using the active products of thorium as a substitute for radium is due to Professors Rutherford and Soddy, who have recommended that the manufacturers of the Welsbach gas mantles should first separate from the tons of thorium they require its radio-active portions. The products that could thus be obtained would be those claimed as a new find by Dr. Bailey. Radio-thorium is an extremely interesting body according to current views. Thorium changes first to meso-thorium, then to radio-thorium, and then to thorium X and a series of other products. Thorium itself emits alpha rays, meso-thorium emits beta rays only, radio-thorium gives out alpha rays, and thorium X gives out alpha rays. Meso-thorium, radio-thorium, and thorium X lose a half of their radio-active powers in seven years, two years, and four days respectively. There is a further extremely interesting chemical property to be noted. When thorium is precipitated by ammonia the precipitate consists of thorium and radio-thorium, which bear so close a chemical relation that they cannot be separated, while from the solution thorium X and meso-thorium can be recovered. As has been already stated, meso-thorium emits only beta rays, but from it radio-thorium giving alpha rays, is evolved in a comparatively short time, and it is possible to collect the whole of the radio-activity of large masses of thorium in minute quantities of matter. It is conceivable that pitchblende may prove to be a more convenient source than the Welsbach mantles for the production of radio-thorium, and it is probable that radio-thorium, from whatever source it can be best commercially obtained, will prove of very considerable medical value. The fact that it can be cheaply procured may render it to a large extent a substitute for radium.

AGGLUTININS, OPSONINS, AND LYSINS.

IN a second report on the haem-agglutinins, haem-opsonins, and haemolysins in the blood obtained from infectious and non-infectious diseases in man, made by Dr. L. S. Dudgeon to the Royal Society at its meeting on March 4th, it was stated that the blood in 14 cases of typhoid fever showed haemolysis on nine occasions. Those instances in which haemolysis occurred when the immune serum was added to normal red cells terminated fatally. In the remaining cases this action was demonstrated when normal serum was added to the immune red cells. Auto-haemolysis was proved twice, once during an attack of paroxysmal haemoglobinuria, once in a case of tertiary syphilis. Iso-haemolysis was found several times when normal serum was added to immune red cells, less frequently with immune serum added to normal erythrocytes. Auto-agglutination was an extremely rare phenomenon. In one instance spontaneous and auto-agglutination occurred, and in this case auto-haemolysis was also proved. Further experience showed that iso-agglutination occurred in normal blood, but not auto-agglutination. Haemolytic agglutinins were present whenever haemolysins could be demonstrated. The specificity of haem-agglutinins had been proved, and the absolute specificity of bacterial and haem-agglutinins had been completely demonstrated. The agglutination resulting from the interaction of a serum and certain red cells could be completely prevented by previously saturating this serum with the specific red cells heated to 60° C. for

one hour. Saturation of the serum with melanin failed to produce any effect. Haemo-phagocytosis was often well marked. The phenomenon usually resulted from the interaction of immune red cells, normal serum, and normal leucocytes. Haemolysins, agglutinins, and opsonins might be present together in a certain sample of serum, or the opsonins and agglutinins together, or opsonins singly. Usually, the agglutinins and opsonins had a distinct relationship.

TREATMENT OF SLEEPING SICKNESS.

THE report of M. A. Broden, Director of the Laboratory of the Belgian Colonial Society at Leopoldville, and of M. Rodhain, Director of the native hospital for trypanosomiasis there for 1907 and 1908,¹ deals chiefly with trypanosomiasis, as did its predecessors, though this part gives more details as to the treatment. Atoxyl, arsenic, the salts of antimony, atoxyl associated with strychnine, with mercury, with orpiment and with the salts of antimony, sublimate and methylene blue, have all been tried, but no more definite results have been obtained than by others, though they believe they have seen definite cure in 3 cases. The first was a lady who contracted the disease in 1903, the same case as has been reported on by Manson and others. She was treated with liquor arsenicalis (Fowler's solution); she remains in excellent health, and has had two children since then. The second case was that of Père D., treated solely with Fowler's solution; he had had no treatment since 1905, and in December, 1907, was in perfect health. The third case was Père R., who was treated first with Fowler's solution, then with atoxyl, and is now apparently quite well. All must allow that the first is an instance of cure, and as she and Père D. were treated with liquor arsenicalis alone, it might be well to go back again to this drug for routine treatment. In addition to the work on trypanosomiasis, the report contains notes on the treatment of syphilis and yaws, a paper on the *Poroccephalus moniliformis*, and remarks on leprosy, on filariae and on intestinal and other parasites. The laboratory is evidently doing useful work.

PLEVNA REVISITED.

THE famous siege of Plevna is not yet forgotten, although the thirty-two years which have passed have dimmed its memory. An interesting account reaches us through the Melbourne *Argus* of a visit recently paid to Plevna by Colonel C. Ryan, M.B., P.M.O. of the Victoria Military Forces, who served with distinction as a surgeon in the Turkish army throughout the Russo-Turkish war, and was the only Englishman present at the siege of Plevna. On his journey from Belgrade, he was reminded when passing Alexinat of a thrilling event. The Turkish position in the 1876 campaign was about a mile from the Servian army, and a certain Ahmed Bey, the strongest man in the Turkish army, overheard his commander-in-chief express a wish that a prisoner could be captured from the Servian lines. Ahmed Bey at once put spurs to his charger, and galloped straight off to the nearest Servian outpost. The Servian vedettes opened fire on him, but he kept to his course, marking down one sentry for his prey. The sentry fired, but missed him, and then, too late, started to run. Ahmed swooped down on him, grasped the man by the collar, and flung him easily across the saddle in front of him. Then he galloped back again, amid a rain of

¹ Rapport sur les travaux faits au Laboratoire de la Société Belge d'Études Coloniales à l'Hôpital des noirs et au Lazaret pour trypanosomies à Leopoldville (Congo, Belge). Bruxelles: Hayez Imprimeur des Académies Royales de Belgique. 1908.

pursuing bullets, and, untouched, delivered up his prisoner to his astonished commander-in-chief! Reaching Plevna, Colonel Ryan was struck by the change in the little town, which now looks prosperous, and where the inhabitants wear European clothes instead of the "frowsy national garb that the Bulgarians used to wear under Turkish rule." On the famous battlefield the old trenches can still be seen, though their sides have partly fallen in, and it was surprising to notice how close the range of fire was in those days, for the Russian guns were never more than 1,200 or 1,300 yards from the Turkish position. The Krishin redoubts were captured by Skobelev at the third battle of Plevna, and recaptured by the Turks the next day, amid scenes of frightful carnage: "these redoubts," he writes, "have been carefully kept in a condition of thorough repair, and they are still exactly as they were at the time of the battle. The No. 1 redoubt is three-sided, the open end when I saw it, a few minutes after the Turks had recaptured it, was filled with Russian dead, Skobelev's troops having utilized the dead bodies of their comrades to make a parapet, from behind which they fired at the charging Turks. This redoubt is now enclosed in a small reserve, called the Skobelev Park, where the memory of the Russian hero is kept green. A great mausoleum looks down upon the scene of the greatest of all the great fights of Plevna." The memory of Skobelev is still preserved with almost religious veneration, and a Bulgarian sentry stands on guard outside the little museum, with his bayonet fixed, protecting the relics of the hero, whose undaunted courage did so much to set Bulgaria free. Colonel Ryan succeeded in finding the house in which he had lodged during the siege, still inhabited by the same family, who gave him a warm welcome and recalled some wonderful adventures of the war. He asked them if they remembered how Skobelev took the redoubt while the bullets were pattering on their red-tiled roof and the family were crying all night; and in his turn he was reminded how he had found two Russian heads in a gooseberry bush in the garden which had been washed down by the flooded stream after the second battle, and how he had run into the house of a friendly neighbour and had eaten his hot dinner while the owner was hiding in a hole in the ground in terror of Russian shells. It will be remembered that Plevna, with between 50,000 and 70,000 men under Osman Pasha, resisted three attacks made on the town by the Russians, who, finding it impossible to take it by assault, determined to reduce it by siege and blockade. For three months the garrison held out, but by the end of that time it had reached the limit of human endurance. The short rations were telling on the men, and typhus, which had broken out with fearful violence, was threatening to annihilate not only the civilians, but the troops also. Thousands of unburied corpses were lying in the streets, the hospitals were overcrowded, and in a deplorable condition. As no assistance came, Osman Pasha determined to try and cut a passage through the Russian lines. Every able-bodied person accompanied the troops, even the doctors and hospital attendants marching with them; whilst 4,000 unfortunates were abandoned for more than three days in the hospitals and ambulances of Plevna, where very many of them died. The march was begun at night in a storm of sleet, but ammunition ran short, and after heavy fighting the Turks were compelled to surrender. The fall of the Bulgarian town decided the war, though it cost the Russians some 50,000 killed and wounded, and delayed the campaign nearly five months.

MINISTERS AND INFANT PRESERVATION.

THE Prime Minister, when he received recently a deputation which presented resolutions passed by the National Conference on Infantile Mortality, was accompanied by the President and Parliamentary Secretary to the Local Government Board, and by the President and Permanent Secretary to the Board of Education. Mr. Asquith, in a sympathetic reply, congratulated the conference on the fact that it had succeeded in obtaining recognition, in the form of legislation or administration, of no fewer than eleven out of the fourteen points stated by it as being of first-rate importance. The three points remaining were: (1) The teaching of girls in domestic hygiene; (2) infant foods; and (3) the extension of the Midwives Act of 1902 to Scotland. Mr. Asquith said that all would agree that in the evils comprised under these three heads were included causes co-operating to bring about bad results; there was the actual waste of child life, and the evil of the growth into womanhood and manhood of children who had never had a chance of developing into normal citizens. He was in hearty sympathy with the deputation, and any practical form of legislation which could be suggested would receive most serious consideration from the Government. Mr. Runciman said that the girls left elementary schools too young, and there was a difficulty in getting a supply of proper teachers of domestic subjects; the Board of Education was endeavouring to persuade training colleges to insist on their students possessing training in those subjects. He hoped that the teaching in the secondary schools would improve in this respect; he hoped much also from the evening schools, and believed that some impression had there been made on girls between 14 and 16 years of age. Mr. John Burns said that since the conference had commenced its labours two years ago there had been a saving of more than fifteen thousand children's lives in one year. The Local Government Board now had a department to inquire into the quality of foods, and he had directed a special investigation into the quality and character of baby foods. As it was found that infant mortality was greatest in houses where there was the largest number of children in one room, he hoped that two or three years' operation of the new Housing Bill, which must become law this year, would make a considerable difference; he also hoped that the Milk Bill would pass.

THE "SEX PROBLEM" IN A NEW LIGHT.

OUR readers need not be alarmed. We have no intention of discussing the eternal question of sex either from the matrimonial or the extra-matrimonial point of view. We do not feel that we have any mission to enlighten the world as to the inner mysteries of the erotic subtleties in which the modern novelist delights, or to find answers to the "obstinate questionings" of those to whom the relations between the sexes seem to be the centre of this universal frame of things. We are concerned merely with a question of nomenclature. Some time ago we were taken to task by a correspondent whom in an unguarded moment we had called a "lady doctor" and, by implication, a "female medical practitioner." "We don't call you," wrote our indignant correspondent, "gentlemen" or "males." She went on to say that a Frenchwoman once said to her, "We have got rid of 'distinctions zoologiques.' Have we? The French lady's—we beg pardon, woman's—remark reminds us of Johnson's old fellow student Edwards, who tried to be a philosopher, 'but cheerfulness was always breaking in.' In the same way we fear zoology will keep breaking in till some higher development

gets rid of sex altogether. In the meantime the difficulty of nomenclature must remain. If we could find equivalents to *medicus* and *medica* the problem might be solved, though even in these simple terms there is a sort of flavour of zoology that might be considered affronting by women who object to being described as female. The word, of course, has fallen upon evil days. Goldsmith wrote,

Where the poor houseless shivering female lies,

when he might just as well have written "woman." But, then, he was the author of a *History of Animated Nature*, and had not lost the sense of zoological distinctions. That "female" was regarded as the very reverse of insulting in Shakespeare's day is shown by Touchstone, when he says to his rival William, "Therefore, you clown, abandon—which is in 'the vulgar, leave—the society—which in the 'boorish is company—of this female, which in 'the common is woman." In the eighteenth century and in the first half of the nineteenth "female" was in constant use by persons who could not be suspected of any wish to insist on zoological distinctions. Fanny Burney, in 1786, described the Princess Royal as "the 'second female of the kingdom." The word "lady" has now, perhaps, suffered degradation from too indiscriminate use. We read the other day in the report of the trial of a "lady prisoner"; she was a mill hand, and should, we suppose, have been described in terms of zoology. When a distinguished lady—again we entreat forgiveness, woman—was elected to the chief magistracy of a borough, the newspapers evidently were in some difficulty about her designation. "Female mayor" would, of course, have been quite too zoological; "mayoress" appears to imply a male—the adjective excites in us no feeling of repulsion—mayor; "woman mayor" was, therefore, the description mostly used. But about our *doctoresses*: "Women 'doctors," which we see is used by a woman writer in an article kindly explaining why they fail, is too likely to be mistaken by the casual person for "woman's 'doctor," a specialist who to our forefathers would have been a "man-midwife." Therefore, as "lady doctor" is proscribed, the sole term left us is "medical 'woman," and we hereby renounce, abjure, and condemn with our whole heart and soul the use of any term in the slightest degree reminiscent or suggestive of zoology in describing those practitioners of the healing art who are not "gentlemen" or "males."

PROPORTIONAL REPRESENTATION.

In the February number of *Representation* attention is called to the progress of proportional representation in South Africa. The draft constitution prepared by the South African National Convention includes the adoption of proportional representation with the single transferable vote for all elections. The steps needed before the change can be introduced include the consent of the legislative bodies of the present colonies and the passing of an Act through the Imperial Parliament. The Proportional Representation Society does not hesitate to believe that the South African legislatures will ratify and the Imperial Parliament sanction the proposal. In the same issue of *Representation* is printed a very able article by Mr. Fischer Williams, the counsel to whom the bill of the British Medical Association for the amendment and consolidation of the Medical Acts has been entrusted, on the general aspect of proportional representation, with special reference to party politics. There is a note also discussing the terms of reference to the Royal Commission recently appointed

to examine the various schemes of election, with a view of advising the Government of this country in introducing a measure of electoral reform. Lastly, we may call attention to a pamphlet recently issued by the Proportional Representation Society dealing with the illustrative election held at Caxton Hall on December 3rd, of which a short account was given on December 12th, 1908. The matter is an extended reprint of the December number of *Representation*, but inasmuch as it places the whole method of the single transferable vote clearly before the public, we have no hesitation in recommending members who are interested in electoral reform to expend the sum of twopence on the pamphlet.¹

THE ROYAL NAVY MEDICAL SERVICE.

IT is understood that the First Lord of the Admiralty, in presenting the Navy Estimates, will make a statement with regard to the Committee which he has appointed to report on the Royal Navy Medical Service. We trust that the recommendations of this Committee may conduce to the welfare of the service, which, with the display of a little consideration and the exercise of a little common sense, might be made exceedingly popular. The extraordinary official secrecy which has been observed with regard to the very existence of the Committee which, it is an open secret, has been sitting for some months under the Chairmanship of Vice-Admiral Sir John Durnford, K.C.B., is a little disquieting, and has given the impression that Mr. McKenna has, perhaps, no very clear policy, and has not fully appreciated his own position in relation to the medical profession and to that not voluble section of the public from whose children all branches of the navy are recruited. The Committee may do good, but, on the other hand, it may do harm. The service is not popular, and its unpopularity is due to the blunders of First Lords who have not been at the pains to understand its problems. There seems some ground to fear that the present First Lord, misled perhaps by the titles borne by the junior ranks of the service, runs a risk of falling into the fatal mistake of supposing that the duties of a naval medical service are mainly surgical, whereas they are mainly medical and sanitary. We pointed out last week in commenting on the Army Estimates that a medical corps had three classes of duties—therapeutic, military (or administrative), and sanitary. If Mr. McKenna has not grasped this elementary principle, he will only add another failure to an already too long list. The First Lord should understand that young medical men of the type the navy wants are neither to be dictated to nor bribed, and unless he has the statesmanship and courage to resist the importunities of theorists unacquainted with the special needs of the navy, and faddists who would arrest all scientific progress by the muzzle and the question he will not succeed. The matter is not primarily a medical question; whether the number of young medical men who enter the Royal Navy Medical Service in any year is twenty or forty is not a question which seriously affects the economics of a profession with between thirty and forty thousand members. But Mr. McKenna's action in this matter is being closely watched by thousands of anxious parents, rich and poor, and it is no exaggeration to say that his decision will influence tens of thousands of votes at the next general election.

¹ The pamphlet and the journal are obtainable from J. H. Humphreys, Honorary Secretary Proportional Representation Society, 107, Algeron Road, Lewisham, or through Messrs. W. H. Smith and Son's bookshops.

FAYRER MEMORIAL PRIZE.

THE officers of the Indian Medical Service on the active list have subscribed a fund to found a prize in memory of the late Sir Joseph Fayrer, to be awarded at each half-yearly examination to the lieutenant on probation I.M.S. who obtains the highest number of marks in the subject of Pathology at the conclusion of the course at the Royal Army Medical College. The prize will consist of a medal with, in addition, a gift of books, should the proceeds of the fund permit. The memory of Sir Joseph Fayrer will always be honoured and cherished by those who knew him, and the prize will, it is hoped, assist in perpetuating his memory among the younger generation of officers who had not the privilege of knowing him personally.

THE Prince and Princess of Wales paid a visit, on March 10th, to the Royal College of Surgeons of England. Their Royal Highnesses were accompanied by Sir Frederick Treves, and were received at the College by the President, Mr. Henry Morris; the Conservator, Professor Arthur Keith; and the Secretary, Mr. S. Forrest Cowell. Their Royal Highnesses were conducted over the Hunterian Museum, and afterwards proceeded to the Council Chamber, where a special collection of specimens was displayed. The visit lasted about two hours.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

The Army Medical Department.—In introducing the Army Estimates last week Mr Haldane said: Now I wish to say a word or two about the health and well-being of the troops. I do not go into the figures of the wastage, though a remarkable diminution is shown in the statement which has been circulated. There is no department of the army to which we owe more than to the Army Medical Service. It was started by Mr. Brodrick in 1902, and has gone on continuously ever since, growing on the lines which he laid down, and the effect of it is that the wastage not only in war but in peace has diminished in the most remarkable way under the direction of Sir Alfred Keogh, to whom the army owes a great deal in this regard as the Director-General of the medical service in the army. There has been a very great improvement progressively in the last six or seven years in the health of the troops. For instance, there has been a very great decrease in the number of those invalided out compared to what it used to be. Then there has been a great decline in what I may call preventive diseases, and in places like the Mediterranean, largely owing to the work of men like Colonel Bruce and other officers in the Army Medical Service, Mediterranean fever and other diseases like that have almost completely disappeared. We have got to another stage, and that is inoculation against enteric. My honourable friend the member for Sleaford will be happy to know that our inoculations are all voluntary; but the result of that system, as far as it has gone, has been a remarkable diminution in the number of patients suffering from enteric disease, and very much brighter conditions for those on duty. The most recent changes that have been made in the case of medical development are the Malarial Commission, which is doing very good work, and the organization of the work of the Antienteric Inoculation Committee, and a very valuable Committee of Experts of very high standing, who have been sitting to inquire into the physiological effects with regard to the food and training and clothing of the soldier. They have remodelled the system of training under conditions which not only render it better, but get rid of the awful disease which we used to have in the army called soldier's heart, which was no doubt due to the stretching of the heart due to the somewhat exaggerated mode of training. There are other things that have been done. The question of sanitary training of officers is most important, so that going on the field there should be

officers who would know exactly what should be done in the way of providing conditions which would make disease unlikely. With that object examinations for sanitary purposes have been introduced for lieutenants on promotion. There are one or two minor matters which I may mention. A curious thing used to be the number of rejections of recruits because of the defective condition of teeth. We thought that that could be to some extent obviated. Some money was taken in the Estimate for seeing whether we could in the district treat recruits for their teeth so as to make them capable of passing the medical test. About 3,500 recruits who would have been rejected last year on account of defective teeth have had them put right at a cost of 6s. 8d. each, and have been able to recruit. We also succeeded in treating 3,500 other men actually serving at a cost of 5s. 9d. each to the taxpayer. I need not trouble the House with other details.

The Position of the Private Soldier.—A discussion on the social conditions of the private soldier's life was raised by Mr. Geoffrey Howard on going into Committee on the Army estimates. He advocated increased facilities for promoting temperance and more thorough training for employment in civil life after discharge from the army. In the course of his reply, Mr. Acland spoke of the improved facilities for education of young soldiers, and the improved sanitation of barracks, on which £16,000 would be spent this year. In referring to the sexual morality of the army, he said there had been a great change for the better during the last five or ten years. The result of the co-operation by chaplains, medical officers, and other agencies had been that whereas in 1897, of the six named groups of diseases which caused discharge from the army, the group of diseases due to this sort of excess came second (it was nearly the worst of all in 1897), in 1907 it had fallen to be practically the least of all. Putting it into figures, it amounted to this: That whereas in 1897 the discharges due to these diseases were 2.5 per 1,000 of strength, they had now fallen to 0.3 per 1,000. The admissions to hospitals were one-sixth of what they were ten years ago. Among other statistics showing evidence of improved health, there had been a decline of deaths from 1,336 to 1,091, and the number invalided had declined from 3,736 to 2,317. Towards the end of the evening Mr. Lupton made a protest against inoculation for typhoid fever, and concluded there was no justification for the practice. It was a degrading method, not a step in advance, but a retrograde step, taking us back 100 years. At this point the Prime Minister moved the closure, which was carried. The main question was then put, and the House went into Committee. On Tuesday night in Committee Mr. Lupton again raised the question of inoculation for typhoid, and referred to the proposal to inoculate for syphilis, which Mr. Haldane repudiated by an emphatic shake of his head. Mr. Lupton quoted some medical authority to the effect that soldiers inoculated for typhoid took twenty-nine days to recover, and the percentage of deaths was 6.5. With regard to Malta fever, he said the improvement was due to better sanitation. He also pleaded for vaccination to be voluntary, and ended by a denunciation of conscription. The vote for the men was then agreed to.

The Notification of Infectious Diseases.—Mr. Tyson Wilson asked the President of the Local Government Board if he could state under their separate headings the number of infectious diseases that it was compulsory to notify that were notified in England and Wales during 1908, with the number of deaths that occurred from each disease. Mr. Burns replied that the information obtained by the Local Government Board on this subject related to London and 256 boroughs and urban districts in England and Wales. Particulars with respect to the year 1908 were being collected, but the returns were not at present complete. The information obtained as regards the year 1907 was summarized at page xcii of the last annual report of the Board. In a later answer Mr. Burns said that he was informed by the Registrar-General that the only infectious diseases which were not ordinarily required to be notified for which he could state the number of deaths in England and Wales for any portion of 1908 were measles, whooping-cough, and diarrhoea. The figures for each quarter of

1907 and 1908, as published in the Registrar-General's quarterly returns, were as follows:

ENGLAND AND WALES.

	Measles.	Whooping-cough.	Diarrhoea.
1st quarter, 1907 ...	3,351	2,775	1,020
2nd " " " ...	4,219	3,036	1,077
3rd " " " ...	2,313	2,283	3,811
4th " " " ...	2,527	1,942	4,396
1st quarter, 1908 ...	2,460	3,804	1,011
2nd " " " ...	2,149	2,900	1,078
3rd " " " ...	1,129	1,593	11,119
4th " " " ...	2,172	1,257	4,689

Water Supply.—Sir George White asked the President of the Local Government Board last week whether his attention had been called to the condition of the water supply at Terrington St. Clement and other places in the district of Marshland, North-West Norfolk, where many families were dependent upon pit or pond water, with the consequent danger to health; and, if so, whether he was willing to grant a local inquiry into the circumstances. Mr. Burns said that his attention had been called to the condition of the water supply of this district, and he had been pressing on the rural district council the need of their dealing with the matter. The district council had within the last few days applied to him to direct a local inquiry on the subject, with a view apparently to the formulation of a scheme of water supply. The application was now under consideration, but he would point out that it was the duty of the district council themselves to take such measures as might be necessary to secure a proper supply of water for their district, and to determine in the first instance on the scheme to be adopted for this purpose. Mr. Leif Jones asked a further question as to legislation to obtain powers to take water rights, and Mr. Burns replied that if it were possible to get through this year a bill giving local authorities greater facility of access to water supplies he should be disposed to take that step.

Tuberculosis in Milk Cows.—Mr. Ellis Davies asked the President of the Local Government Board whether, in view of the report of the Royal Commission on Tuberculosis in Animals that the disease might exist in the living animal without detection save by the tuberculin test, the Board proposed to insist upon such test in the case of all milk cows; and, if so, whether the Government proposed to compensate the owners of animals which were proved to be tuberculous only by the application of the test, and were subsequently destroyed in the interest of public health. Mr. Burns said that he had in preparation a bill dealing with the better supply of milk and the regulation of dairies; but he could not undertake to say in anticipation of the introduction of that measure what proposals the Government might decide to make with regard to the matters referred to.

Carcasses Seized for Tuberculosis.—In answer to Mr. Courthope, who asked the number of carcasses seized, and how many were condemned for tuberculosis, Mr. Burns said that he was not at present in a position to give the information desired. The medical officers of health had been requested to include in their annual reports for 1908 information as to the action taken under Section 117 of the Public Health, 1875, or Section 41 of the Public Health (London) Act, 1891, as the case may be, and they had been also requested to state the number of carcasses and parts of carcasses condemned for tuberculosis. When this information was obtained he would be happy to grant a return on the subject.

Fibroid Phthisis in Quarry Workers.—On Tuesday, in answer to Mr. Ellis Davies, Mr. Gladstone said that the Committee on Industrial Diseases had reported that the incidence of fibroid phthisis in slate quarries had been established in some instances. In the case of the Cornish mines special rules were established after an

exhaustive inquiry, which showed extensive mischief owing to the use of machine drills. In the case of the slate mines and quarries, there was no evidence that the disease prevailed to a serious extent, and much of the drilling, he understood, was done by hand, involving much less exposure to dust. The question, however, of extending the precautions adopted in the Cornish mines to all cases in which dust of an injurious character might be produced by rock drilling had not been lost sight of, and the working of the existing rules was being carefully watched. The Royal Commission on Mines was, he believed, shortly to reach that part of its inquiry which had to do with conditions of health and safety in metaliferous mines and quarries, and it would be desirable that the matter should be considered by them.

Infant Mortality.—In answer to Lord Castlereagh, who asked about the death-rate of infants born in workhouses and workhouse nurseries, and how it compared with the ordinary infant death-rate, Mr. Burns said that he had seen the figures on this subject in the Minority Report of the Royal Commission. He did not think that these figures could properly be compared with the ordinary figures of infant mortality, for, as the authors of the Minority Report themselves recognized, it was never satisfactory to compare the mortality rates of institutions having only limited numbers of inmates placed under exceptional circumstances and having peculiar antecedents with those of the population at large. The subject was of much importance, and it was being carefully examined.

The Inebriates Acts.—Mr. Cecil Harmsworth asked the Home Secretary whether, before introducing a bill to amend the Inebriates Acts, he would consider the desirability of collecting evidence, whether by means of a Select Committee or otherwise, as to the efficacy of some of the methods of drug treatment in the cure of inebriety. Mr. Gladstone replied that the recent Departmental Committee advised that "no good purpose could be served by making a further or more extended investigation into the value of existing methods for treatment of inebriety by the use of drugs." He concurred in that opinion, and was not prepared to delay legislation, which was urgently required.

The Report of the Vivisection Commission.—Mr. Gladstone informed Mr. Gooch last week that the preparation of the report was being proceeded with, but owing to the large amount of evidence that had been taken and the technical nature of much of it, considerable labour was involved, and it was difficult to indicate exactly when the report was likely to be presented.

Street Accidents (Medical Fees).—Mr. Weir asked the Home Secretary if he would state the fees payable to doctors and veterinary surgeons respectively for attending accidents in the streets and for giving evidence thereon in police courts. Mr. Gladstone replied that the following were the fees payable: (1) To medical men: For attending casualties, 3s. 6d., if between 7 a.m. and 7 p.m.; 7s. 6d. if between 7 p.m. and 7 a.m. For giving evidence, 10s. 6d. for each case, if within two miles from residence, and for each additional mile 2s. 6d., with a maximum total fee of 21s. (2) To veterinary surgeons: For attending injured horses, 10s. 6d.; for slaughtering, if necessary, 5s., or, if a Greener's humane killer was used, 10s. 6d. He understood that veterinary surgeons never had occasion to give evidence in accident cases.

The Public Health Officers Bill to amend the law relating to the tenure of office of medical officers of health and sanitary inspectors, and for other purposes, was introduced by Sir Walter Foster on Tuesday last. The second reading is put down for April 16th.

New Bills.—The following new bills have been introduced and ordered to be printed: The Nurses' Registration Bill, by Mr. Munro Ferguson; the Nurses' Registration Bill (No. 2), by Mr. Findlay; the Asylums Officers' Superannuation Bill, by Sir W. Collins; Death Certificates (Charges) Bill, by Mr. Gill; the Oaths Bill to facilitate the administration of oaths by uplifted hand, by Mr. Bramsdon; and the Public Health (Provisional Orders) Bill, by Mr. George Thorne.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

LEEDS.

THE MEDICAL INSPECTION OF SCHOOL CHILDREN.

THE arrangements which have been made for the medical inspection of school children by the Education Committee of the Leeds City Council have excited a good deal of interest among the members of the profession of Leeds, and call for some comment. It will be remembered that the Medico-Political Committee of the British Medical Association circulated among all the Divisions a report dealing with many points arising in connexion with the medical inspection of school children, including the various methods and rates of remuneration. It was pointed out that the inspection might be carried out by a whole-time medical officer with junior or assistant medical officers under him. In this case it was suggested that the salaries should be not less than £500 for the senior and £250 for each of the juniors, travelling and other expenses being met by the Committee. In the event of payment per head being adopted, it was suggested that 2s. 6d. a head should be the minimum fee. For part-time officers the Association recommended a system of payment already in operation in London—namely, that the salary should be based upon the time devoted to the work, and that the minimum should be £50 per annum in respect of each school session of two hours per week. The opinion of each Division was specifically asked for as to the rate of remuneration, and at a meeting of the Leeds Division held on January 29th, 1908, a resolution was passed approving of these rates. It is indeed matter of regret that the Divisional meetings of the British Medical Association are not well attended in Leeds. On this occasion the attendance was only 22, the total membership of the Division being 155. The report had, however, been circulated and the business announced on the agenda paper, and so the opinion expressed must, especially as the meeting was unanimous, be regarded as that of the Division. After much deliberation the Education Committee recommended to the City Council the appointment of a medical officer to devote the whole of his time to the inspection of school children in Leeds at a salary of £350. They also recommended the appointment of medical practitioners to assist in the work; these to be prepared to devote one, two, or three half-days in the week to medical inspection at a remuneration of one guinea for each half-day's service of thirty examinations. When these recommendations came before the City Council, they were modified in this respect—that the appointment of the whole-time medical officer was negatived, and it was arranged that the general administrative work should be placed in the hands of the present medical officer of health. The number of part-time medical officers to be appointed was discussed, and though no actual number was decided on, it was generally understood that a large number would be appointed. The matter next came before the Executive Committee of the Division in this way. When the advertisement—which was inserted in the local press—was sent to the BRITISH MEDICAL JOURNAL, the discrepancy was at once noticed between the scale of fees formerly approved of by the Division, and the much lower scale of fees in the advertisement. The Medical Secretary therefore communicated with the Secretary of the Division, and a meeting of the executive, followed at the earliest possible date by a meeting of the Division, was held to discuss the matter. This meeting was held on January 20th. There was an attendance of twenty-two members. Dr. T. Wardrop Griffith was in the chair, and explained the reasons for the meeting being summoned. He also stated what was common knowledge—that the Leeds Education Committee during their deliberations had been approached by Dr. Hawkyard and Dr. Woodcock, the chairman and secretary of a newly formed association of medical practitioners of Leeds and district. Both these gentlemen, who are members of the Division, were present and spoke at the meeting. The general feeling of the meeting was that the pay was quite inadequate. If on the one hand an afternoon's work was to be regarded as two hours' work, then the examination of thirty children other

than in a perfunctory manner was not possible; if, on the other hand, the thirty children were examined in anything approaching a satisfactory manner the amount of time to be devoted to them would render the remuneration of one guinea absurdly small. It was confidently asserted by one speaker that notwithstanding the statement in the advertisement that the number of cases to be examined was thirty, if it was found—as Dr. Wardrop Griffith was certain it would be found—that this could not be done in two hours, the payment of one guinea for the afternoon's work would still be forthcoming, but he pointed out that this was certainly not what was said. It was understood that a large number of applications had been sent in, many of them by members of the Division. It was felt that it would not be right at the eleventh hour to call on members either to withhold applications or to withdraw them. There was no doubt that an adequate number of applications would have been received even if every member of the Division had loyally fallen in with such a suggestion. All that was done, therefore, was that the chairman, Dr. Griffith, along with Dr. Eddison, Dr. Hawkyard, and Dr. Allan, the Secretary of the Division, were appointed to seek an interview with the Education Committee as soon as possible and lay the views of the Association before them. This was done, and the deputation, which consisted of Dr. Griffith, Dr. Hawkyard, and Dr. Allan, went before the Committee on January 27th. When Dr. Griffith, who acted as spokesman, pointed out the impossibility of medical men examining thirty cases in two hours or two and a half hours, he was immediately met by the statement of one of the members, which was ratified by the chairman, that it did not matter within reasonable limits how long was taken over the examination; the essential thing was that one guinea was the fee for thirty examinations, and that if desired the medical men might spread these examinations over two visits. Dr. Griffith's obvious rejoinder to this was that in this case the amount of time necessarily and very properly devoted to the examination of thirty children was going to be very inadequately represented by the payment. The chairman then told the members of the deputation that the committee had not decided on the scale of remuneration without consultation with representatives of the medical profession—which, of course, they knew—and that no less than eighty-nine applications had been received. Dr. Griffith said he knew that this was the case, that the remuneration was, all the same, far too small, but that, fully acquainted as he was with the character and calibre of most of the men who were applying, he did not doubt the work would be conscientiously done. Though the two representatives of the new association doubtless did their best to obtain fair terms for the profession, yet one cannot help feeling that had the members of the Leeds Division of the British Medical Association attended the meetings in good numbers and regularly, an important question of this kind would not have been decided in the way it has, but in harmony with the legitimate and reasonable wishes of a united profession. The scheme as above described has not passed without criticism from other quarters, and it has had to be modified as the result of an interview with Dr. Newman, Chief Medical Officer of the Board of Education. The general supervision of school inspection will remain, as was suggested, in the hands of the medical officer of health; under him will be a part-time general medical practitioner, who will act as supervisor of the other medical inspectors; and, finally, the number of medical inspectors to be appointed is not to exceed twenty. The matter must for some time be in the experimental stage. It is confidently anticipated that the committee will become alive to the error of its ways, and raise the rate of remuneration. Indeed, it is by this expectation that many men have been influenced in their decision to send in applications.

MANCHESTER AND DISTRICT.

THE COST OF MEDICAL TREATMENT OF SCHOOL CHILDREN.

It is very evident that the education authorities in Manchester and the surrounding districts have a serious task to face if they really intend to prevent the whole cost of the medical treatment of school children falling on the

rates. They seem very properly to have made up their minds that those parents who can afford to pay for any treatment advised by the school inspectors shall be compelled to provide it at their own expense. Assurances have been given by the authorities of Manchester and Salford and other districts that only certain classes of cases shall be dealt with for the present, and that treatment shall be provided free only when the parents cannot otherwise obtain it. On the other hand, it is clear that many parents will take the ground that they, as the natural guardians of their children, have the sole right to decide when their children shall undergo treatment, and that if the authorities advise treatment of any sort the authorities must pay for it. If this contention were granted it would certainly result in many parents deliberately shutting their eyes to the necessity for treatment, and relying on the medical inspectors not only advising but furnishing any treatment needed, and unless the authorities are quite firm and resolute now at the beginning of the movement, there is danger that the whole of the treatment will fall on the rates. Another argument that is being used by people who are quite well able to pay is that in many cases treatment is advised not so much in the interests of the individual children as in the interests of the community, and in such cases the community should pay the cost. The free treatment of all cases of infectious fevers in the municipal fever hospitals has lent some force to this argument, as it is almost unheard of for the municipal authorities to ask even well-to-do people to pay for such treatment, except, of course, where private wards have been used. That the authorities are fully alive to the danger of a serious imposition on the rates by those who have no right either legally or morally to free treatment is shown by two cases which appeared in the law courts last week. At Eccles a man, described as a commission agent and presumably in a position to pay for treatment, was charged at the instance of the Eccles Education Authority with having unlawfully and wilfully neglected his daughter, aged 10, in such a manner as to be likely to injure her health. The Town Clerk stated that the charge was made under Section 1 of the Prevention of Cruelty to Children Act, 1904, which provided that any person over 16 years of age having charge of a young person under 16 years of age, who wilfully neglected a child in such a manner as to cause injury to its health, including the sight, was guilty of a misdemeanour; the Town Clerk added that this also implied the absence of reasonable care.

The Town Clerk and the Medical Officer of Health, who is also school medical inspector for the borough, showed that the defendant had received several notifications to provide his daughter with spectacles. The medical inspector said that he had examined the girl four times since last September, and that she was suffering from myopia of such a degree that it was quite necessary for her to have spectacles. The school teacher at the school where the girl attended said that she was suffering, both physically and mentally, from defective eyesight; that she could not see to read without placing the book close to her eyes, which caused great eye-strain; and could not distinguish figures on the black-board. As this was the first case brought before it under the Act, the bench inflicted a mitigated penalty of 20s. and costs. Another case, which is not exactly one of medical treatment, but will fall under the care of the school medical inspector, came before the Manchester County Bench. The Levenshulme Education Committee summoned a man for the cost of a number of meals supplied to his two children. Altogether the children had had thirty meals each, at a total cost of 10s. The defendant pleaded that he had not been able to provide meals, as he had not had a full week's wages for many months. The education officer, however, proved that in the last two months he had received £9 12s. 6d. in wages. The magistrates ordered him to pay 2s. 6d. a week till the amount was paid, together with the cost of the summons. While those cases may serve as warnings to other parents, it is to be hoped that the authorities will not allow their present good intentions to be gradually weakened and worn away by repeated attempts to obtain free treatment on the part of those who can well afford to pay private practitioners.

RETURN CASES OF SCARLATINA.

It was stated last week in the Salford Town Council that complaints had been received from Pendlebury that cases of scarlatina had been dismissed from the Salford Sanatorium before they were free from infection, and that as a result fresh cases had occurred. The chairman of the Health Committee promised to make careful inquiry into any specific case that could be brought forward. A short time ago, too, the Salford Corporation was threatened with an action for damages on the ground that a patient with scarlatina had been dismissed too soon from the sanatorium, with the result that other children had caught the infection. The greatest sympathy must be felt with the health authorities, and especially with the medical superintendent of the sanatorium, when any of these cases arise, as it is known that they cause the greatest anxiety, and that every possible precaution is taken to prevent them. Medical men of course know the difficulties; they know that it is impossible to say at any time that a particular patient is free from infection as the nature of the infection is quite unknown, and the demand of the public for an absolute statement cannot be complied with. The Salford authorities act on the presumption that desquamation has nothing to do with infection, and cases are sent out while still freely desquamating. The public, on the other hand, have a firm conviction, which not so long ago was encouraged by authorities, that the peeling is infectious, and on this account nothing is so common for doctors in Salford to hear as the statement that there has been carelessness in dismissing patients when really the greatest possible care has been exercised. As a matter of fact, it is stated by the authorities that since they have begun to neglect desquamation as a factor in infection and to pay special attention to nasal and other discharges there have been fewer return cases than formerly, when the cessation of desquamation was regarded as the test of freedom from infection. The total number of return cases in Salford is not stated, but in Manchester, in 1907, there were 86 cases notified as having possibly arisen from eighty patients discharged from Monsall Hospital. It should be stated that in reckoning these, no "time limit" was taken; all cases being included, however long the interval between the discharge of the first and the onset of the second case. If a month is taken as the time limit, as is done in some towns, the cases which were possibly infectious when discharged form 4.5 per cent. of the total number discharged. In 1906, when patients were only detained in hospital four weeks, the number of returns was much higher, and accordingly, in 1907, the medical superintendent thought it advisable to regard cases apparently free from infection at the end of four weeks with some suspicion, and to detain them a few days longer. On this account, probably, the return cases are much fewer. At Baguley Sanatorium the patients causing return cases are 2.36 per cent. of the total number discharged. There can be no doubt that secondary cases would have been far more numerous if all primary cases had been treated at home, that is to say, the existence of return cases cannot be taken as any argument against hospital treatment.

Far more serious is the question whether return cases are not more fatal; in other words, whether the fever hospital does not tend to maintain a more severe type of the disease. On analysis of the deaths in Manchester the Medical Officer of Health finds that return cases do actually show a higher case fatality, but the fact that they generally occur at a younger age than the average cases may partially account for this, as the disease is more fatal the earlier in life it occurs. After all there does appear to be a special infectivity derived from aggregation in hospitals, and Dr. K. Gordon agrees with Dr. Niven's suggestion that there is in each patient an intrinsic infection derived from the original ailment, and an extrinsic infection obtained from other patients, the nose and nasopharynx acting as a sort of incubating chamber for germs derived from other patients. This is supported by the fact that, by separating convalescent from acute cases the return cases have diminished. Dr. Gordon now goes even further, and, though it is quite impossible to have separate wards for severe and mild cases, tries to do everything possible to isolate bad types of the disease. Screens are placed round their beds hung round with sheets damped with izar, and the nurses attending the bad cases have to use special gloves which are kept in bowls of izar at each

patient's bedside. In view of this special hospital infection it is not desirable to urge removal to hospital of cases that can be properly isolated at home, but Dr. Niven does not think it reasonable to contemplate dispensing altogether with removal to hospital, though it has frequently been suggested of late years. It may be noted that at the present time there is a very extensive epidemic of scarlatina at Stockport, and the hospital has been so crowded with cases that several have had to be refused admission, and it has not been possible to provide proper accommodation for the isolation of cases of diphtheria and enteric fever.

LIVERPOOL.

THE HESWALL POOR LAW SANATORIUM.

At a recent meeting of the Liverpool Select Vestry it was decided to confirm a recommendation of the Finance Committee declining to sanction an extension of the Heswall Joint Hospital. The proposal was to add to the institution a bungalow, to cost £1,000, for the provision of twenty-five beds. The Vestry's share would be £400. For the extension, it was argued that it would materially reduce the average cost per bed of the entire establishment. The majority of the board, however, inclined to the opinion that the results of the treatment in the way of "cures" were not such as to justify any further expenditure. It was stated that this opinion was based on the view that the benefits conferred were not in any sense commensurate with the expenditure involved, which now worked out, it was stated, at £500 per bed. It was pretty generally admitted that the great drawback was that most of the patients who were sent to the Heswall Hospital did not come within the control of the vestry at a time when the disease could be successfully dealt with, but only sought assistance when they were in a state which was practically hopeless. It was stated that at the present time the Health Authorities of the city had under consideration the question of treating consumptive cases in one general scheme for the whole city, which would, of course, be more economical.

BIRMINGHAM.

BOVINE TUBERCULOSIS AND THE BANG SYSTEM.

The Health Department of the city of Birmingham has issued a report by Mr. Dexter, Deputy Chairman of the Health Committee; Dr. Robertson, Medical Officer of Health; and Mr. Malcolm, Veterinary Superintendent, on the prevention of tuberculosis amongst cattle in Denmark. These gentlemen visited Denmark with the special object of studying Professor Bang's method of eradicating the disease. The system employed aims at the gradual eradication of infection by segregation and isolation rather than by slaughter. The only animals destroyed are cows with tuberculosis of the udder and "wasters" which exhibit well-marked and extensive generalized tuberculosis, and are, therefore, manifestly dangerous to others. The essentials of the method are: (1) The application of the tuberculin test to entire herds; (2) the complete and permanent separation of all reacting from non-tuberculous animals; and (3) the gradual rearing up of a healthy stock from the reacting animals. This last object is attained by the separation, immediately after birth, of all calves born of tuberculous cows, and the feeding of such calves, either with normal milk or with milk heated to a temperature sufficient to kill any tubercle bacilli it may contain. The writers were very favourably impressed with what they saw, and report as follows:

1. Bang's method has proved itself in Denmark during the past sixteen or seventeen years to be a practicable and economical method of ridding herds of dairy cattle of tuberculosis.

2. We consider it to be a method which may equally well be introduced into this country with a probability of even better results ensuing than have been met with in Denmark.

3. The method is somewhat slow in operation but has the advantage of not being costly, and of causing little or no disturbance to the trade of the milk producer. (A warning is necessary against the indiscriminate slaughter of cows reacting to tuberculin on account of the cost which such slaughter occasions.)

4. The difficulties met with in practice are neither numerous nor serious, and, apart from those relating to accommodation and the labour involved, they are likely mainly to arise from

the want of appreciation of the fact that tuberculosis is an infectious disease, spread like other infectious diseases in a number of ways.

Amongst the examples of successful treatment by the Bang system the writers quote the experience of Sir O. S. Oxholm in South Zealand. He commenced the Bang treatment in 1895, and then found that, out of his total stock of 448 cattle, 350, or 78.1 per cent., reacted. In 1908, thanks to the continuous application of the Bang system, he possessed 784 presumably healthy cattle; all these were tested, and only 19, or 2.4 per cent., gave a reaction. The Birmingham deputation asked Sir O. S. Oxholm what it had cost him to eliminate tuberculosis from his herds, and were informed that, instead of there being any loss, he had derived considerable profit. The milk producer with a clean herd reaps a substantial advantage, inasmuch as he is allowed to sell his milk as "baby milk," which, by Government order, must be the product of cows certified free from tuberculosis; and the retail price of such milk is approximately twice that of ordinary milk. The authors conclude their report with the following recommendation: "Pending the introduction of a Government bill, very good results could, we think, be obtained by Birmingham, and at very little cost to the corporation, if dairy farmers supplying milk to the city were offered the necessary tuberculin and veterinary advice on the lines set out in the report of the medical officer to the Health Committee on May 11th, 1908." In the report referred to it is proposed:

That in the first instance dairy farmers supplying Birmingham with milk should have their herds tested at the expense of the municipality, and should have the benefit of the advice of the corporation veterinary staff, provided they discarded wasters, separated the infected from the non-infected, and carried out certain other simple precautions which would in due course eliminate tuberculosis from their herds at very moderate cost to the municipality, and probably at an equally small cost to the dairy farmers.

LEICESTER.

HOSPITAL SATURDAY FUND.

The report of the Hospital Saturday Fund for the city and county of Leicester for the year 1908 contains some rather striking figures. The fund has only been some eight years in existence but in that short time has made remarkable progress. Eight years ago the total subscribed by workpeople was little over £3,000, while last year this amount was more than quadrupled in spite of the fact that during that period Leicester was in the throes of serious trade depression. A sum of £12,000—approximately that collected—far overtops, in proportion to population, the collection of any other Hospital Saturday Fund. Furthermore, the expenses of collection and administration, which appear to be well under 4 per cent., compare most favourably with those of the majority of similar funds in other cities. Of the total available sum some 70 per cent. is annually allotted to Leicester Infirmary, and the rest spent on the maintenance of patients in the Fund's own and other convalescent homes. In view of this fact, the success of the Hospital Saturday Fund at Leicester may be regarded as in no small measure a testimonial to the infirmary, and as a sure proof of the esteem in which that institution is held by the population. It has been estimated, indeed, that in one way and another the infirmary receives an amount equal to one-half its annual expenditure from the working classes. If other Hospital Saturday committees could show equally good results there would be little fear for the continued prosperity of voluntary hospitals, and no room for even academic discussions as to the possibility of replacing them by rate-supported institutions.

WALES.

GLAMORGAN SANITARY COMMITTEE.

Midwives.—At the quarterly meeting of the Sanitary Committee of the Glamorgan County Council, Dr. Williams, county medical officer, reported that there were on the last published roll of the Central Midwives Board the names of 648 women residing in the administrative county. From replies received by him it appeared that 554 had signified their intention to practise, and there were 60 uncertified midwives practising in the county who could continue to do so until April, 1910. Of the 554 certificated practitioners, 457 had received their certificates on account of

having been in bona fide practice since July, 1901. The remaining 67 held certificates of training. The report stated that Nurse M. Evans, the inspector under the Midwives Act, had during the quarter visited 231 midwives, of whom 6 had attended the lectures at the University College, Cardiff, but had not presented themselves at the examination of the Central Midwives Board. On the motion of Dr. T. H. Morris, it was decided to recommend that a communication be sent to the Local Government Board calling attention to the number of women receiving theoretical training in midwifery, and expressing the opinion that only a small percentage of those receiving that education would be able to pass the examination, and that, inasmuch as many of those unable to pass were practising, and would probably continue doing so after 1910, it would be difficult for the inspectors of midwives to find out those who were legally practising unless the Local Government Board could see its way to ask the Government to put a column in the Register of Births, so that the person registering could give the name of the midwife in attendance, and thus enable her to be visited by the inspector. A report was also presented upon the training of midwives, in which it was suggested that the number of 45 free studentships in theoretical and 9 scholarships in practical instruction should be reduced, and scholarships awarded for complete courses of training, which would result in at least 25 fully-trained midwives being turned out annually without further cost, instead of 9 as at present. The report was referred to the Education Committee.

Health of the County.—Dr. Williams's quarterly report upon the health of the county showed that 295 cases of diphtheria had been notified, as against 209 in the previous quarter; 910 cases of scarlet fever, as against 610; and 112 cases of enteric fever, as against 110. Dealing in detail with the districts of the county, the report stated that the public slaughterhouse at Barry was much appreciated, but nothing further had been done in the matter of providing a public slaughterhouse for Briton Ferry, where it was urgently needed. The committee decided to inform the Briton Ferry Urban District Council that unless something was done by the next meeting of the committee the facts would be reported to the Local Government Board. It was also decided to send a similar communication to the Penarth Urban District Council. It was decided that no grant be made to the Barry Council in respect of its infectious diseases hospital until certain repairs, extensions, and additions had been carried out. It was reported that the negotiations between the Briton Ferry Urban Council and the Neath Rural Council for the provision of a joint hospital had ended, the latter council having decided upon an institution of their own. It was stated that the infectious diseases hospital at Penarth was the most appreciated public institution in the district; little or no trouble was now experienced in persuading parents to allow their children to be taken to the hospital for treatment. It was stated that Bridgend had been very free from infectious diseases of late years. In regard to the Garw and Ogmore infectious disease hospital at Blackmill, Dr. Williams stated that it was quite evident the hospital was beginning to be appreciated in the district for whose benefit it was intended. The committee, after considering the report, decided to urge the Gelligaer Urban District Council to proceed with the provision of an isolation hospital, and to ask the Caerphilly Council to open the hospital it had provided.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

THE REWARD OF MERIT.

AFTER a long illness, Dr. Winslow, Medical Officer of the Scrabby Dispensary District, co. Cavan, had some weeks ago to resign his appointment, owing to age and bad health, and asked the guardians for superannuation. There was a long wrangle at the board meeting as to what, if any, superannuation should be given him after his fifty years in their service. The majority at the meeting were in favour of giving him £80 a year, which was £20 less than he would have been entitled to under the Civil Service scale, but, owing to some informality, this decision

was held to be invalid by the Local Government Board, and another meeting of the guardians was called to consider it. The observations of sundry of the guardians at that meeting are instructive. Some of them were of opinion that, owing to the large salary—£120—paid him for so many years, he was not entitled to any pension, as he should have saved enough out of it to retire on. Others said that, as there had never been any complaint against him, he ought to get something, but certainly nothing like £80 a year. Still a third party would give him £80 a year, because he could not live more than a couple of years to draw it. Eventually, by a majority, they allowed him £60 a year as a special favour. How any Irish Poor Law doctor can desire to remain an employee of such people when he has the chance—if the members of the profession exert themselves—of being freed from such thralldom, it is not easy to understand, yet it would seem that many Irish Poor Law medical officers are opposed to a State service.

WOMEN'S NATIONAL HEALTH ASSOCIATION.

The annual meeting of the Derry branch of the Women's National Health Association was held in the Union Hall, Derry, on March 5th. The Mayor occupied the chair, and there was a large attendance. The report showed that there was a membership of over 1,100 women; a successful babies' club had been established, and several public sanitary measures had been considered, which were strongly supported by the speakers.

BANDON WORKHOUSE.

The Local Government Board has recently reported most unfavourably as to the general condition of the Bandon Workhouse. When the inspector went round he found the dormitories dirty, and on the majority of the beds the sheets were filthy, the matron acknowledging that she was unable to say when the sheets had been last changed, there being no regular time for doing so. There are practically no baths for the main part of the house, as the two baths which are in the tramp wards are unfit for use, and are never used by the inmates. The men are supposed to have washing basins, but they could not be produced on the day of the inspector's visit. There are no proper sanitary arrangements. The closets are old-fashioned and primitive, and very difficult to keep clean. The sheets in the hospital were by no means as clean as they should be. Proper baths, with hot and cold water laid on, should be provided for the hospital. The removal of lunatics to another institution was advised, as the cells used by five non-dangerous lunatics were not fit for human habitation, the remaining lunatic cells being occupied by a man with skin disease and an old blind pauper.

CORK JOINT HOSPITAL BOARD.

At the monthly meeting of the Cork Joint Hospital Board held on March 8th, a deputation on behalf of the United Trades Association made representations as to prepared joinery imported from England and intended for the new sanatorium works at Streamhill. The president of the United Trades Association told the committee that there was no necessity for the importation of such work, for there were plenty of competent men available to do the work in Cork. He pointed out that there was a clause in the contract that all the carpentry and joinery work should be done locally, and he considered that the importation of this work was not only helping to continue the want of employment in the city but it was a slur on the character of the Irish workman. After some discussion it was decided that the contractor must be made to abide by the terms of his contract and not to use any imported joinery. Mr. Creagh announced that it would be necessary to make formal application to the Board of Works for the loan of £12,000, to be drawn in sums of £1,000. A sinking fund had been created, as the 1d. in the pound was being raised throughout the county, and his firm conviction was that a considerable portion of the cost of the building should be defrayed out of the proceeds of the rate accumulating. That would leave a larger sum for administration when the institution was erected.

THE London Hospital Medical College Endowment Fund, to which an anonymous benefactor recently gave £20,000, has received a further gift of £100 from Miss N. A. Aiston for the advancement of research at the college.

Correspondence.

SLEEP AND WANT OF SLEEP.

SIR,—The BRITISH MEDICAL JOURNAL of February 27th contains a suggestive paper by Dr. Robert Farquharson on sleep and want of sleep and a leading article on sleep and hypnotics, giving a concise and very instructive survey of the principal hypnotics in use. I am no longer in practice, but I have been so during more than fifty-five years, and may, therefore, be allowed to say a few words on this subject.

Dr. Farquharson justly directs attention to the late Arthur Durham's almost forgotten researches, leading him to the inference "that the physiological condition known as sleep results from an anaemic condition of the brain." I wish by no means to contest the correctness of the experiments of him whose memory is dear to me as to all who knew him intimately; but I cannot say that anaemia explains all the phenomena connected with sleep, and Dr. Farquharson seems likewise unable to do so. I have repeatedly discussed this subject with Mr. Durham, and he quite agreed with me that it was impossible for him to assume that the results of his experiments were sufficient to explain the phenomena of sleep in man. Amongst the different points of our conversation was also the question specially mentioned by Dr. Farquharson, why "short naps of five to ten minutes, snatched in the middle of work, or even of play, are so extraordinarily refreshing?" It is not the momentary state of the circulation and supply of blood alone by which we can account for this; it is probably connected with peculiar changes in the nerve cells of the brain; but I am as little able sufficiently to explain it now as I was at the time when Mr. Durham and I discussed the question more than forty years ago.

I venture to add a few words about the use of remedies for want of sleep. I fully concur with Dr. Farquharson's remark as to the necessity of paying attention to idiosyncrasy, which exists to a greater or lesser degree with regard to all the hypnotics—most commonly, in my experience, with opium and its derivatives, but also with the apparently most innocent, such as bromides; these have caused, for instance, in a strong man, after a few ordinary evening doses, in a case of Mr. Arthur Durham's, of urethritis, symptoms like ataxia at two trials, once with the potassium, once with the sodium salt. On the other hand, many of us, I think, are inclined to condemn a remedy as useless and dangerous when a more careful trial, sometimes in combination with another remedy, would show it to be very useful. Thus, chloral hydrate is at present too sweepingly condemned, while I have used it with great advantage, sometimes alone in ordinary doses, but more frequently in small doses, combined with bromides and with morphine, in persons who could bear the latter. I have, for instance, prescribed very often, according to circumstances, 3 to 6 grains of chloral hydrate, with 10 to 15 of a bromide and 5 to 8 minims of liq. morph. hydrochlor. In most cases such combinations had a beneficial effect, and in none that I know of an injurious one. We must bear in mind that the combination of smaller doses of several remedies allied in their action has frequently a better action than the single remedies in larger doses, and that in this way unwelcome effects can be avoided. I need not say that in every case I have endeavoured to dissuade patients from continuing the remedy without the well considered advice of their doctor. Other hypnotics, too, I have often combined, such as bromural and chloral hydrate, trional and chloralamide, trional and paraldehyde, veronal and paraldehyde. Long experience, however, has convinced me that hypnotics are much more frequently given than is either necessary or useful, and, further, that many persons fall into the habit of taking them, and through this injure their nervous or circulatory or digestive system, or all three, and their resisting power to disease, and cause premature senility and death. I have generally prescribed hypnotics only in mental distress or bodily pain, or prolonged wakefulness from intrusion of anxious thoughts, and occasionally for night travelling and sea voyages.

A certain amount of sleep is necessary and is the "chief nourisher in life's feast," but many persons indulge in too much sleep and injure their nervous and circulatory systems. The difference in different people in the amount of sleep required is very great: children and growing persons require much sleep, while the majority of adults require much less. Experience has taught me at an early period, that there are many people who without injury to their health can do with comparatively little sleep (four and a half to five and a half hours), and need not on account of short hours of sleep, or frequent interruptions of it, fly to the use of hypnotics. I could give many instances and will mention my own case. I have never been a good sleeper, not even at school, and later on in active life, often from anxiety about my work, my hours of sleep were short and often interrupted; I was very seldom more than six hours in bed, and mostly woke literally ten to twenty times and oftener during the night, and only rarely had short naps during the day. My health in the 86th year shows that the limitation of sleep has done me no harm. Mostly when I was able to persuade my patients that lying awake part of the night, and frequently waking, did them no harm, they gradually felt that they could do with little sleep, and often began to sleep better.

I may add that I made many trials on myself with different hypnotics as they were introduced into practice, as well with each separately as also with several in combination; I did this, however, not to procure sleep for myself, but in order to learn their action and the advisability of using them in others.

I have also tried many other little helps to procure fair nights without hypnotics, but it would require much more space, and I have already trespassed in this matter.—I am, etc.,

Grasse, Alpes Maritimes, March 2nd.

HERMANN WEBER.

SIR,—I see by the discussion going on in the JOURNAL that the physiology of sleep is not much more settled than it was when I wrote about it in 1875, and I do not think the suggestion I then made has ever been discussed. May I, therefore, briefly repeat it for the consideration of those who are versed in the advances which physiology has made since that date?

In the introduction to the third edition of my book *On Winter Cough*, I attempted to explain the relation between certain cases of "spasmodic asthma" and of "sneezing asthma" and the phenomena of sleep. I discussed the subject at considerable length, but I will now only extract the passages in which my hypothesis as to the physiology of sleep is stated as follows:

The hypothetical explanation which I have suggested (of these cases) is an intermediate state common to all the given antecedents; and in answer to the question, What is this intermediate state? I suggest that it is distension of the perivascular system of canals with liquor sanguinis migrated from the red-blood vessels; that in the normal state an immediate return of fluid from the perivascular system to the red-blood vessels takes place on the return of normal circulation in them, and that the abnormal condition which exists in the peculiar cases under consideration consists in a derangement of this power of instantaneous change of place between the contents of the two sets of vessels (p. xxxii). . . . If this hypothetical explanation which I have suggested should prove to be correct, it would apparently involve the conclusion that, if a contracted condition of the red-blood vascular system of the brain is a necessary condition of sleep, this is coincident with the migration of liquor sanguinis into the perivascular canals, by which concurrence of circumstances the necessary element of equally-balanced cerebral pressure is maintained, while the element of functional excitability, due to the abundant circulation of red blood, is removed. Thus functional rest without arrest of nutrition is secured. If this reduction of red-blood circulation with the substitution of liquor sanguinis saturation is the cause of sleep, it will account for many of the phenomena of cerebral disease and their relation to sleep, and to ordinary causes of cerebral hyperaemia which are unexplained by the theory of cerebral anaemia without perivascular saturation (p. xxxiv).

I have been too long out of the arena of physiological discovery to be competent now to re-enter upon the discussion of this subject; but I think the hypothesis is worth the consideration of those whose knowledge is up to date, and who are now specially interested in the very important question of sleep.

In conclusion, to turn from theory to practice, let me give two prescriptions, which have served me "so many a

good turn" in procuring sleep for my patients, that I hope they may do the same for others. First, instead of *shutting* the eyes, as people generally do when they want to go to sleep, let the patient be ordered to *strive to keep the n open* to the last possible moment. It is surprising how often they will then *close in sleep* in spite of every effort to keep them open. The room should be feebly lighted, but on no account dark; darkness is often fatal to sleep.

HORACE DOBELL, M.D. (retired).

Parkstone Heights, Dorset, March 5th.

A MEDICAL DEGREE FOR LONDON STUDENTS.

SIR,—The scheme for establishing a system of conjoint examinations between the Royal Colleges and the London University demands the closest scrutiny and the most careful safeguarding lest its results should be found as nugatory as those of every attempt hitherto made to provide a degree on fair terms for London medical students. As I understand the scheme set forth in p. 607 of your issue of March 6th, it provides as follows:

The London University is to continue to confer its degrees on the terms it now requires, but these degrees are to be termed "honours degrees."

The Royal Colleges are to continue to confer their diplomas as heretofore, under the conditions and titles that now obtain.

The University and the Royal Colleges are to combine to conduct examinations of students who shall have spent not less than four years in study at London medical schools and hospitals, and who shall have complied with certain other conditions, and those who pass these examinations will not receive a diploma from either college, but will receive a pass degree from the University.

The University will, therefore, in future confer two sets of degrees: M.B., B.S., M.D. (and query M.S.) Pass, and M.B., B.S., M.D., and M.S. Honours.

The Conjoint examinations will continue, but will henceforward be held by three conjoint bodies instead of by two; the number of conjoint examinations preliminary to qualification will be increased from two to three, or, including the preliminary general examination, from three to four; the reward for passing the conjoint examinations will be an M.B., B.S., instead of the L.R.C.P., M.R.C.S., and, on passing a further conjoint examination, the M.B., B.S. may be converted into an M.D. This is the scheme as I understand it, and it is open to the following criticisms:

The great obstacle to the attainment of the medical degrees of the London University by the ordinary student is not the difficulty of the professional examinations, high as the standard of these examinations is; the main obstacle is the matriculation examination. If the scheme is to be a practical success, it is essential that the University shall admit, to the conjoint examination, candidates who have passed, in lieu of matriculation, the entrance examinations now sanctioned by the existing Conjoint Board. Will the University consent to this? It is over the matriculation examination that it has shown itself most impracticable. If it does consent, are these preliminary examinations to stand as matriculation for the pass medical degrees alone, or are they to be homologated with the other alternatives to matriculation, or to serve as a portal of entrance to all the degrees of the University? If the former, will not the medical pass degrees be held in disesteem, and their holders to have entered the University by a back door? If the latter, the main obstacle to the attainment of the existing university degree will have been removed, a much larger contingent of London medical students will go for the honours degree, the necessity for the Conjoint pass degree will be diminished, and its reputation will be still more affected.

What are to be the facilities or difficulties of the holder of the pass degree in proceeding to the honours degree, should he desire to do so? If the entrance examination for the pass degree is a special examination, admitting to that and to no other degree of the University, then, in order to proceed to an honours degree, the M.D. pass must

go back to school and work up his preliminary subjects while he is in the middle of his professional career—precisely the barrier that keeps so many able men from attaining the University degree under the existing regulations. If, on the other hand, he may proceed to the honours examinations without suffering this indignity, then there will be one rule for the Medical Faculty and another for the other faculties, which will scarcely satisfy the University.

The substitution of three professional examinations for the two in the present curriculum before the Conjoint examinee can obtain his diploma is a handicap to the London medical student in comparison with the alumni of other universities. The grievance of the London medical student is that for the same expenditure of time, labour, and money for which a provincial student can obtain a university degree, the London student can obtain the Conjoint diplomas only, which, although well known in the profession to represent professional attainments equivalent to a university degree, are not so regarded outside the profession. What the London student wants, and what he is entitled to, is a degree obtainable on the same terms as those on which he now obtains his Conjoint diplomas. If he is offered a degree that cannot be obtained except on terms more stringent than those open to the provincial medical student his grievance is not removed. If this degree, obtainable on more stringent terms than degrees in provincial universities, is yet to be regarded as a one-horse degree, avowedly inferior to all the other degrees of the University and rendered specially easy to suit weaker brethren, his grievance will be not removed but intensified. Insult will be added to injury. He will still be giving more and getting less than his provincial compeer.

What will be the several standards of the four grades of degrees? Presumably the M.B., B.S., M.D. and M.S. Honours will stand at their present level, and the standard of the pass degrees will be lower. Presumably, also, the M.D. Pass will be a higher degree, and will satisfy a higher standard than the M.B., B.S. Pass, but what relation is the M.D. Pass to bear to the M.B., B.S. Honours? It can scarcely be adjusted to a lower standard. If so adjusted, or if adjusted to an equal standard, would not the M.B., B.S. Honours men have a legitimate grievance in that, having proved themselves of superior, or at least equal, attainments to the M.D. Pass men, they would be fobbed off with a degree titularly inferior? If, however, the M.D. Pass is to be a higher standard than the M.B., B.S. Honours, what will be the difference between the M.D. Pass and the M.D. Honours, and what will be the advantage of the whole arrangement?

What was the object of the Royal Colleges in referring the matter to the Royal Commission? Either Statute 123 of the University of London provides the necessary powers for the constitution of the scheme or it does not. The report of the delegates is made on the assumption that it does. Why, then, incur the uncertainty of convincing the Royal Commission? Why seek the delay inevitable in the presentation and effectuation of the report of a Royal Commission having such an immense scope of reference, a report that will require an Act of Parliament to bring it into effect? Is it that the delegates suspect that the University will not consent to the scheme except under the compulsion of an Act of Parliament?

Lastly, to my mind, the scheme as adumbrated exhibits one defect that seems to me capital. It makes provision for the future only. It offers no redress to the immense number of medical men who by taking the L.R.C.P., M.R.C.S., have proved that they have attained the standard of proficiency required for a university degree, but have not obtained that degree. I am of opinion that any powers the Royal Colleges may obtain for the conferment of a degree should be retroactive, and that the holders of the conjoint diplomas should be at liberty to exchange these diplomas for the new degree of M.D.

I do not say that the difficulties and defects that I have pointed out are enough to render the project impracticable, but it cannot be denied that together they are very grave. It is possible that the working scheme the delegates have in their minds may provide against most or all of them; but the views of the University have yet, it seems, to be ascertained, and the University has hitherto steadily

resisted every attempt to make its degrees more accessible to London medical students.

Looking to the inherent difficulties of the scheme; to the uncertainty of securing the consent of the University and the approval of the Royal Commission; to the likelihood that the scheme, even if accepted by these bodies, will first be so modified as to deprive it of much of its value; to the long delay that must of necessity occur before the report of the Royal Commission can be enforced by Act of Parliament—it seems a pity that the Royal Colleges did not take their courage in both hands, and apply for Charters which would give them the power themselves conjointly to confer a degree of M.D. without requiring any concurrence with the University. This I believe to be the best, if, indeed, it do not prove to be the only, practicable solution of the difficulty.—I am, etc.,

London, W., March 4th.

CHAS. MERCIER.

STATE REGISTRATION OF NURSES.

SIR,—We have read with much interest the account of the movement in favour of the State registration of nurses, which appeared in the *BRITISH MEDICAL JOURNAL* for February 13th—a movement with which we are in complete sympathy. We write, however, to point out that there is a large body of nurses—namely, fever nurses—which so far has been quite ignored by the various associations which have interested themselves in State registration. This has been due chiefly to the fact that, though it is a body of very considerable magnitude, it is only recently that its organization has been taken in hand. Nearly all the nurses to whom we refer are in the employment of municipal authorities, and they constitute a very distinct and important service. The Fever Nurses' Association has been formed for the purpose of organizing this service, furthering its interests, and raising and maintaining its standard of training. We are of the opinion that any scheme for the State registration of nurses which does not recognize the special training the fever nurses receive, will be incomplete. Nurses in fever hospitals consist principally of two classes—the one, of those who, after a three years' training in a general hospital or infirmary, spend some time in a fever hospital to gain special experience; the other, of those who enter the fever hospital without having undergone the previous general training. The latter often spend several years in fever work. We wish it to be clearly understood that we in no way advocate the establishment by the State, in connexion with the registration of nurses, of a separate register of fever nurses, such as it is proposed to institute for mental nurses. We hold, however, that those nurses who are eligible for enrolment on a State register should be definitely credited with the additional experience they have gained in the nursing of fevers, and, in supporting any endeavour towards the establishment of State registration of nurses, we shall at the same time do all we can to secure the due recognition of the fever nurse.—We are, etc.,

E. W. GOODALL,
President.

F. FOORD-CAIGER,
Chairman of Executive Committee.

JOHN BIERNACKI,

L. A. MORGAN.

Honorary Secretaries, Fever Nurses'
Association.

London, March 1st.

SOUTHWOLD LIBEL CASE.

SIR,—My attention has been drawn to an appeal in the *BRITISH MEDICAL JOURNAL* of February 6th, p. 353, asking for subscriptions to defray the "heavy expenses" which two members of the Association "have incurred as the result of the recent action which they were called upon to defend."

The appeal does not state upon what grounds we are asked to support these gentlemen, who have apparently been cast in heavy damages for a malicious libel upon a brother practitioner.

The appearance of this appeal in the columns of our *JOURNAL* would certainly appear to indicate that it is issued with the sanction of the Association, if not even with its official approval.

To the ordinary self-respecting medical man it would not appear to be a case in which much sympathy is re-

quired, as these gentlemen have been found to have committed what seems a very cruel offence, and not some heroic action worthy of a reward.—I am, etc.,

London, W., Feb. 6th.

FRED. J. SMITH.

THE REPORT OF THE PUBLIC HEALTH COMMITTEE.

SIR,—There seems to be a singularly extravagant development amongst the members of the medical profession, both individually and collectively, of that predatory instinct which is always on the alert to appropriate another man's "job."

It was seen a little while ago, in the endeavour to take away the public vaccinator's work and distribute it amongst all and sundry, regardless of the fact that the net result would have made it of very little benefit to anybody. And what has been the result? Well, soon there will be whole-time public vaccinators at £250 a year or less, and so much less will go to the emoluments of the general practitioners.

I have been struck recently with the extremely short-sighted policy of the general practitioners, as shown in the *JOURNAL* and at the Branch meetings, by trying to abolish all medical officers of health who hold any private practice. What will be the result? That all those general practitioners who are now medical officers of health, or nearly all of them, will have their appointment confiscated; for it is absurd to suppose that the salaries will be such as to tempt men to give up anything like a moderate practice; and the net result will be that some thousands a year will be diverted from the emoluments of the general practitioners of the country.

We have let the midwifery go; we have let school inspection go, and apparently we are trying to throw the health appointments overboard; and all that remuneration and prestige will be lost to the general practitioners, and there will be just as many of them left to "cut each other's throats" for what private practice is left.

Is it not patent to anybody who has eyes to see that the whole end and aim of the powers that be is to get all the practice out of the hands of private practitioners, and substitute a public service of "inferior" specialists, midwives, lady inspectors, oculists, school inspectors, public vaccinators, Public Assistance doctors, medical officers of health, etc.; in fact, a big staff of more or less junior officials who will be hidebound by red tape and sweated as much as the man with only one string to his bow can be?

Would it not be better for the general practitioners to try and keep as much of the work of this nature as they can, and as they are unquestionably better fitted for than "small specialists"?—I am, etc.,

A GENERAL PRACTITIONER WHO IS ALSO A
RURAL M.O.H.

March 9th.

RURAL M.O.H.

MUNICIPALIZATION OF HOSPITALS.

SIR,—Although not in favour of hospital municipalization, may I point out that the arguments quoted in the *BRITISH MEDICAL JOURNAL* of March 6th, p. 625, from the speech of Dr. Horrocks, are hardly those that will satisfy the Socialists.

"Every one who paid rates would be eligible for admission." This now obtains in the fever hospitals, and the paying of rates is no bar to admission in most general hospitals, which are open practically to all.

"The pushing and energetic would soon occupy the beds to the exclusion of the poor and needy." Here, in practice, the opposite occurs; for in general hospitals the better-off keep out the poor; whereas in municipal (fever) hospitals the poor get "relatively" vastly better value from their illness, and their cases have paramount care.

"The staff, instead of being voluntary workers, would become officials, and . . . it would be necessary to reduce the number, as it would be impossible to pay so many of them adequately." True, but the "officials" would then be mostly "whole-time" men, and would be paid. The staff of the fever hospitals, asylums, army, navy, prison service, infirmaries, public health service, School Board service, police medical service, clubs (&c.), limited companies, etc., do their work no less well because they receive salaries more or less adequate. Doubtless the personnel of the directors would be inferior socially, but in many

cases would not differ materially from what at present exists—for example, in Edinburgh the Lord Provost is at the head of both the infirmary and the municipal hospital (fever) management.

For the large endowed hospitals with traditions, municipalization is impracticable, as it would involve huge litigation over the moneys left in trust by the charitable, but I believe it would do in the case of smaller general hospitals about to be built in rising working-class neighbourhoods, and that the younger generation of practitioners would profit by the salaries, assuming always that the present declension in private practice continued on its apparently irremediable down grade.—I am, etc.,

Edinburgh, March 9th.

JAMES CAMERON.

THE METROPOLITAN PROVIDENT MEDICAL ASSOCIATION AND THE TREATMENT OF SCHOOL CHILDREN.

SIR,—There is an error in your note referring to the meeting of the medical officers attached to the Metropolitan Provident Medical Association on March 2nd. The meeting was not well attended by the profession; of the 114 doctors on the staff only about a dozen were present. In my remarks I stated that the poor attendance was probably due to the unusually severe weather causing so much extra work.

An amendment was proposed by myself to the second resolution—that the association would only undertake the treatment of school children whose parents or guardians were unable to pay doctors in the ordinary way. This would prevent the contemplated departure from the lines on which our provident dispensaries have hitherto been worked—namely, to provide medical attendance for those who cannot pay in the usual way. Moreover, the amendment would be in accordance with the views expressed by the British Medical Association in its report on provident dispensaries. Mr. Leon and Sir William Bousfield spoke in opposition to my amendment, which, I regret to say, found no second.—I am, etc.,

London, W., March 8th.

HENRY H. STURGE.

OPHTHALMIC SURGEONS AND SPECTACLE VENDORS.

SIR,—It is to be hoped that before long some rules will be made to regulate the relationship between spectacle vendors and ophthalmic surgeons, and in certain directions it is perhaps desirable that there were some means of enforcing a higher standard of professional conduct on a very few of the gentlemen who practise ophthalmic surgery. The following events will perhaps convince a casual reader that some change is necessary if irregular practice is to be held in check and properly qualified men are to have fair play. A nurse on holiday at a watering-place in Scotland advertised her address extensively in the local papers stating that she would be glad to see ophthalmic patients, particularly those requiring the testing of errors of refraction. It seems that this woman happened to be a nurse at an ophthalmic hospital in England, and was employed by the surgeons there for the purpose of testing such cases.

A somewhat similar incident was brought to light the other day—namely, that for one ophthalmic hospital an attendant in an optician's shop in the town in which this hospital is situated does a large portion of the refraction testing. I think that thereby the authorities responsible for this hospital simply help to propagate quack practitioners. A patient happened to come into my hands who had been tested in this shop, possibly by the attendant who was employed at the hospital. The correction which was given was for each eye cylinder minus 1, axis horizontal, the real correction was spherical plus 2.5 for each eye.

Ophthalmic surgeons should steadfastly, not only in their own interests but in the interests of the public, set their faces against practices of this sort. To some extent members of the profession are blameworthy in the matter. A child complains of some little difficulty of vision, and a large number of the medical fraternity do not send that child either to an ophthalmic surgeon or to an ophthalmic hospital, but recommend it to a shop to have its eyes examined. They do not seem to be aware of the fact that it takes even the best trained surgeons from an hour to an hour and a half to obtain accurate and trustworthy results,

and that any error in the correction may spell disaster for that patient so far as sight is concerned.

In other respects changes are needed. Thus, in a British ophthalmic hospital members of the staff have been known to admit, with full knowledge of the fact, so-called optologists to their clinics. It seems to me that such conduct is entirely wrong, and I hope that some day or other persons who in this way countenance irregular practitioners will be adjudged guilty of conduct infamous in a professional sense. One of the worst cases of the countenance of irregular practitioners occurred not long ago, when a member of an ophthalmic congress introduced to its meetings a spectacle vendor in such a manner that the gentlemen attending the meeting understood the man to be an ophthalmic surgeon.

There are other matters in the relationships of ophthalmic surgeons to spectacle vendors which ought to be put right. Some years ago an advertising spectacle vendor put in as a special bait in his advertisements that if he did not manage to fit the patients himself he would recommend them to have recourse to a skilful and experienced oculist. One general practitioner in the town sent a number of patients to this optician, and they were every one of them referred, with a card, to one particular ophthalmic surgeon. Would the General Medical Council regard this as canvassing for patients?—I am, etc.,

March 2nd.

SPECIALIST.

THE TREATMENT OF CANCER.

SIR,—It is interesting to contrast two papers which appeared in the JOURNAL of last week on the subject of cancer. Mr. Sampson Handley appears to look at treatment in a somewhat peculiar way. He says in effect that because cancer occasionally cures itself a cure for cancer cannot exist, but he somewhat illogically excludes Coley's fluid. He goes on to make this statement: "For every cancer which reaches its full clinical development, it may be that a hundred are strangled in the process of birth, etc." This is rather strange in a scientific paper when supported by not a vestige of evidence. Mr. Handley also suggests as suitable cases for experiment advanced cases of cancer of the stomach. Instead of doing this, I would advise trying any favourable line of treatment on an early case, say of ulceration of the tongue. The correct treatment at present is to operate after mercury and potassium iodide have failed to check the ulceration. Medicine is given to show if operation is necessary, then why not go a step farther and try something else for say two weeks? I did this successfully in a case five years ago. Whether the diagnosis of epithelioma of the tongue was correct or not I am not prepared to say, but I can state that had I not treated him for cancer empirically the man would have had half his tongue removed.

In contrast we have Dr. Fenwick's paper—simply a record of clinical facts. I would like to suggest that any one trying his treatment should keep a record of the condition of the blood, and especially of the differential white cell count. It would be especially interesting to know what happens to the white cells in the cases which suppurate.—I am, etc.,

London, W., March 9th.

GEORGE E. KEITH.

SIR,—The scientific and lucid exposition of the natural cure of cancer in the JOURNAL of March 6th is of great interest to all of us; but it is of especial interest to me, in so far as in the last paragraph Mr. Sampson Handley indicates a line of treatment advocated with emphasis by me six years ago—"the open-air treatment," with a reduced diet. In my argument I instanced the case of such treatment of tubercle, but did not push the analogy, because I did not know then as I do now that the natural cure of cancer is by the same process as tubercle—that is, fibrosis. That position being demonstrably established by Mr. Handley, the case in favour of my proposition is greatly strengthened, and all that remains is to put it to the test of experiment. I quite, however, disagree with his recommendation that "under no circumstances whatever should the treatment be recommended as a substitute for operation, if operation is possible."—I am, etc.,

London, E.C., March 9th.

HOPE GRANT, F.R.C.S.E.

SIR.—Mr. Fenwick, in his paper on the treatment of cancer by potassium bichromate, mentions my name as having refused to treat a simple small rodent ulcer. This is absolutely incorrect.

Before making such a statement, Mr. Fenwick might easily have communicated with me; but that does not appear to be his idea of medical etiquette.

In the only other case of mine where to my knowledge his treatment has been tried, my first and only intimation that he was in attendance was a message brought by a son of the patient, saying, "Dr. Fenwick says you will not be wanted at our house any more, as he will look after mother."

Shortly I was again called in to soothe the last hours and sign the patient's death certificate.—I am, etc.,

T. FRANKISH, M.B.

March 6th. Honorary Surgeon, Victoria Hospital, Accrington.

THE APPLICATION OF MENDELIAN CHARACTERS TO MAN.

SIR.—We have, I think, almost reached the limits of usefulness in this discussion, but it is desirable to sum up the stages of it, so that your readers may appreciate whether I have made a "surrender" or "gone off at a tangent."

1. In a public lecture given by Dr. Drinkwater a statement was made that Nettleship's nightblind pedigree was an illustration of Mendelism, and sensibly gave in the offspring of abnormals the required 50 per cent. of abnormals. There was no warning whatever that Dr. Drinkwater was calculating the offspring of abnormals in a hitherto unheard-of manner—namely, by omitting all those cases in which an abnormal chanced to have no abnormal children. Hundreds of returns have been made by the Mendelians, but not one before Dr. Drinkwater has adopted this remarkable method of calculation.

2. I pointed out in your columns that the hitherto accepted Mendelism showed that in the Nettleship pedigree there were 137 abnormals and 235 normals in the offspring of the abnormals (various other counts, ranging from 131 to 137, may be made, until several obscure points in the pedigree as at present constructed are cleared up, but such divergencies do not alter the matter). This is no approach to 50 per cent.; indeed, the odds against a deviation so large as this are more than 10,000,000 to 1.¹

3. Dr. Drinkwater wrote to the *BRITISH MEDICAL JOURNAL* explaining the manner in which he had calculated his percentages—namely, by omitting the offspring of all abnormals who had only normal offspring, and justifying it on the ground that he believes that dominance changes with the mating. He cited Ewart and Thomson as believing that it changed in the mating, not, apparently, because he held this view himself, but because it might confirm his view that it changed with the mating.

4. My reply was, and is still, that this change of dominance may be perfectly correct—or the reverse; but that:

(a) It is destructive of the first Mendelian principle of dominance;

(b) It renders the second Mendelian principle of segregation of small value, because the segregation will not take place in the recognized Mendelian principles.

(c) It would invalidate much Mendelian work which has included in calculating percentages the offspring of abnormals with only normal offspring.

(d) It renders Mendelism of no service to the medical profession, because it will be impossible to say until an abnormal has completed his family whether he is a true Mendelian abnormal or a Drinkwaterian spurious abnormal with a capacity for producing only normal offspring. Further, by a judicious change of mate, even if he had had abnormal offspring, he might improve matters, and have unaffected children!

Shortly, my contention is that Dr. Drinkwater's method of dealing with Nettleship's pedigree is destructive of Mendelism, which, whether correct or incorrect as a description of hereditary phenomena, is at least a logical whole. It is quite possible that a determinantal theory of alternative characters may eventually account for many such cases, and when this has been done the credit will lie largely with the movement dating from Mendel. But,

¹Those who wish to study whether their observations are in accordance or not with theory will find the determination of such odds fully explained in Westergaard's *Grundzüge der Theorie der Statistik*.

until it is done, I for one shall continue to protest against the current tendency among what I shall venture to term the free lances of Mendelism—as distinct from the staff corps—to drag into popular lectures and magazine articles as illustrations of Mendelism cases which can only be termed Mendelian if a method of counting *ad hoc* be invented, or if odds, which only a tiro in the science of observation would overlook, be disregarded.—I am, etc.,

KARL PEARSON.

Biometric Laboratory, University College, March 7th.

ARTERIAL BLOOD-PRESSURE RECORDS BEFORE AND AFTER MUSCULAR EXERTION.

SIR.—Dr. Leonard G. J. Mackey criticizes the conclusion I arrive at in the *JOURNAL* of February 27th when I point to the "improbability that the heart in morbid conditions would be capable of overcoming pressures much greater than 160 to 170 mm. Hg" (Dr. Mackey, in quoting my words, has, I feel sure, unintentionally omitted the word "much"), assuming that this measurement is near the limit of reserve power of the normal heart.

I venture to think that the point which Dr. Mackey overlooks is that the question is one of reserve power. It is, I believe, generally admitted that the reserve power of a hypertrophied heart is less (and less in proportion to the degree of hypertrophy) than that of a normal heart.

Of course every one recognizes the fact that a heart in a case of long-continued high arterial blood pressure becomes hypertrophied, and overcomes greater pressures than the normal heart usually does.

My point is that it is reasonable to assume that such a hypertrophied heart, although working at a higher average pressure than the normal one, is, owing to the fact of its having less reserve power, unlikely to be capable of dealing with pressures much greater than the normal heart can when this is working at near the limit of its reserve power.

—I am, etc.,

London, W., March 6th.

OLIVER K. WILLIAMSON.

PULMONARY TUBERCULOSIS IN CHILDREN.

SIR.—I am very glad to see that Dr. Fisher has drawn attention to the sweeping assertions of Dr. Mary Williams with regard to phthisis in school children.

After a large experience with children, I should be inclined to say that phthisis in school children is one of the rarest diseases. The conditions which are so often mistaken for phthisis are the non-tuberculous conditions of fibroid disease, often with some bronchiectatic dilatations.

The condition seems to arise chiefly from antecedent bronchitis from within and from pleurisy from without. I have frequently had typical cases of fibroid disease, with and without the cardiac displacement that so often accompanies it, brought to me as tuberculosis. I am inclined to think that if the majority of those inspecting children were asked how often they had seen fibroid disease in children the answer would be that it was practically non-existent, whereas I think that if reliable statistics could be obtained they would be found to vary very considerably from those of Dr. Williams.—I am, etc.,

March 8th.

ELWIN H. T. NASH.

RURAL NURSING ASSOCIATIONS.

SIR.—Among other subjects which are now calling for attention from the members of the Association is that of the local nursing associations which are rapidly being established throughout the country. Ostensibly introduced to assist the medical attendant, and to work under his directions in the interests of the sick poor, the nurse in many cases becomes a serious competitor for minor medical and surgical practice. The managing committee consists of a group of the usual well-meaning female busy-bodies, on which the local practitioner is often not in any way represented. A general canvass of the district is made, cases are sought for in all ranks of society, and touting is openly and avowedly practised. Not merely the poor, but the small farmers and tradesmen of the villages are entreated to employ the nurse and midwife, with the assurance that if anything goes wrong the doctor, who has always hitherto attended them, can be called in. In some cases I have been told the nurse makes a friendly call on nearly every case under medical treatment, the usual gossip

ensues, with a criticism of the diagnosis and treatment of the case, not always to the advantage of the medical attendant. In fact, in many parishes an active unqualified practitioner has been introduced, backed up by a body of ladies, whose interest it is to make the thing a success, and the unfortunate doctor finds that, although it is illegal for him to employ an unqualified assistant, he is met by the keen competition of an unqualified woman, not merely in midwifery, but in ordinary medical and surgical practice. In country districts a serious difficulty arises, and one equally injurious to the general public and to the medical profession.

The remedy, in my humble opinion, is to make the representation of the profession imperative on every nursing association, and no association should be recognized unless a medical man is placed on the executive and local committees. Touting should be discontinued, and no member of the British Medical Association should give assistance or sanction to any nursing association that does not loyally carry out these principles.

Least it should be thought I write from personal motives. I would say, "Our withers are unwrung." If the members of the profession will refuse to back up these unqualified practitioners, the difficulty will soon settle itself, but it must be by united effort and loyal co-operation.—I am, etc.,

Leckhampton, March 1st.

WM. MILLIGAN.

Public Health

AND

POOR-LAW MEDICAL SERVICES.

RESIDENT WORKHOUSE OFFICIALS IN THE DARTFORD UNION.

IN the BRITISH MEDICAL JOURNAL of December 19th, 1908, p. 1347, it was noted that the members of the nursing staff of the Dartford Union were at that time in a state of serious dissatisfaction owing to the treatment they were then experiencing under a fresh order of the board; the effect of this order was to deprive them of the sole occupancy of some of their own quarters, other officials of the house having been given permission to share the rooms; the nursing staff was thus deprived of the privacy they so greatly needed when temporarily free from duty with their patients. We now read in the *Dartford Express* that at a recent meeting the board of guardians, after further consideration, has rescinded its former order, and has thereby restored to the nurses the exclusive use of their own dining room. It may hardly be correct for us to assume that the opinion expressed in the JOURNAL in opposition to the views of the guardians has led to this change, but we cannot help thinking and even hoping that it may have accelerated the settlement of an unhappy difference on an important matter, which appears to have been somewhat suddenly sprung upon the nursing staff by the governing body. No doubt the nurses have expressed to the board their gratitude for its final decision, which appears to have effected a restoration to them of all their former comforts and privileges.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Thingoe (West Suffolk Rural District).—Between the census of 1891 and that of 1901 there was a decrease in the population in the rural district of Thingoe of 1,215 persons, but Dr. Scott Kilner bases his statistics upon the population recorded at the last census (14,528). The birth-rate on this basis was 22.9 per 1,000, and the death-rate 13.2. The infantile mortality-rate was equal to 75 per 1,000 births. The District Council will be well advised to take the advice of their medical officer of health and to utilize for cases of infectious disease, other than small-pox, the iron hospital which was erected some years ago. It was intended to be used only for small-pox patients, but has never yet been occupied.

Maldon (Essex Rural District).—The population of the Maldon rural district at the last census was 14,650, showing a decrease of 1,111 persons since the previous census, but the population at the middle of 1908 was estimated by Dr. Thresh at 14,800, and he thinks this is rather below than above the actual population. The birth-rate in 1908 was 24.4 per 1,000, the death-rate 12.7, and the infantile mortality-rate equal to 61 per 1,000 births. In his description of the methods of dealing with infectious disease in the Maldon district, Dr. Thresh states that after the removal or recovery of a patient the house is disinfected. On rare occasions bedding, etc., is removed and disinfected by steam, but the ordinary method of disinfecting by burning sulphur and the thorough cleansing of the infected house produced such good results that apparently no more complicated, troublesome, or expensive process seemed necessary. Comparing the localities in which he had insisted on steam disinfection in practically all cases with those in which such disinfection had not been insisted upon, he had not found the slightest reason to think that steam disinfection was necessary. His experience related to thinly-populated areas, and did not apply to towns.

Medico-Legal.

WORKMEN'S COMPENSATION CASES.

Compulsory Operations.

ON February 18th His Honour Judge Dodd heard an application made by Walter Hall and Co. for the suspension of the compensation paid to Joseph Charlesworth on the ground that if he underwent a slight operation he could resume work. It appeared that respondent was a blacksmith's striker, and on April 7th last year, whilst working in a foundry, got his finger caught under a steam hammer. The finger was seriously injured, and the man was now in receipt of 10s. per week compensation. The finger was bent, and the tendons were so involved that the bent condition must continue, and the application was for an order that Charlesworth should have his finger removed, which operation, he suggested, would place the man in a position to earn as much as before.

Judge Dodd: It is a serious thing to ask the court to say that a man shall undergo a serious operation.

Mr. Clegg, on behalf of the employers, observed that it was impossible for the finger to improve, and that the operation suggested was a simple one.

The Judge: The doctor's view of what is a simple operation is not quite sufficient. They are rather fond of operations.

Mr. J. Raley on behalf of Charlesworth said that his client was not unwilling to undergo an operation, and if the doctors were unanimous that it would do him good he would undergo it at once, but they did not agree. Mr. Raley added that he was going on the principle that a man could not be acting unreasonably if he was following medical advice.

Dr. J. H. L. Allott, of Barnsey, who had examined Charlesworth, gave evidence that he would be better with the finger off. In the course of cross-examination he admitted that there was some slight risk attendant upon the operation.

Dr. Martin, house-surgeon at the Beckett Hospital, said the man ought to have his finger taken off.

Dr. Harold Horne, asked if he advised the man to have his finger taken off, replied "Certainly not," and Dr. Wallis said he agreed with everything Dr. Horne had said, and disagreed with everything Dr. Allott and Dr. Martin had said.

His Honour, who was assisted by Dr. Fryer as medical referee, said it was not unreasonable that the man should desire to wait a little longer before undergoing an operation of this sort, and he therefore dismissed the application with costs.

GIVING NOTICE.

R. R. R. asks what is the usual notice given by a medical principal when he wishes to discontinue his assistant's services.

*. In the case of an indoor assistant, the usual notice given is one month. In the case of an outdoor assistant or the manager of a branch, a longer notice is not infrequently given. It is assumed in these cases that the assistant is paid monthly. Where the salary is paid quarterly or half-yearly, a longer notice would be necessary. The law requires a "reasonable notice," and in fixing what is reasonable the criterion usually is the time when the payments of salary become due. Many principals arrange with their assistants on engaging them what notice shall be given on either side.

MIDWIFERY NURSES' ENGAGEMENTS.

ASTOUNDED.—Our correspondent was unwise in acting as he did. It was his patient who engaged the nurse, and had a right to require her services at the time agreed. The action against him should fail, as the nurse was bound by her previous contract to come to his patient, but unless she explained to her former patient that she might be called away, she might herself be liable for damages. He should place the matter in the hands of his solicitor, if a member of a medical defence society, ask for its assistance.

Medico-Ethical.

The advice given in this column for the assistance of members is based on medico-ethical principles generally recognized by the profession, but must not be taken as representing direct findings of the Central Ethical Committee.

MEDICAL PRACTITIONERS AND DRUGGISTS.

R. T. J.—(1) It is generally recognized that it is not desirable for a qualified practitioner to have his consulting rooms at a chemist's shop, but we know of no rule forbidding it. (2) A qualified chemist who is also a qualified medical practitioner can, if he chooses, carry on both businesses, but it is not a desirable combination.

INTRODUCTIONS TO PRACTICE.

NR.—If no agreement was entered into by either party, and if Dr. A. has finally broken off all negotiations, our correspondent would seem to be free to do as he pleases.

BRANCH SURGERIES.

SANDY LANE complains that a medical competitor took away a good paying patient by establishing a branch surgery in her house; and now he finds that another patient, a midwife, has hung her framed certificate in the window, side by side with the hours of attendance of the doctor.

"* We have repeatedly drawn attention to the manner in which branch surgeries may be abused; but we are not sure that there is any just ground of complaint if a medical man becomes the tenant of the patient of another practitioner and in course of time the relationship of landlady and tenant is converted into that of doctor and patient. With regard to the second point, we agree that it would be better that the two notices should not be hung up side by side, as medical practitioners should be careful to avoid doing anything to suggest that they stand in any special relation to midwives.

MEDICAL PRACTITIONERS AND PROPRIETORSHIP
OF PATENT MEDICINES.

W. H. C. writes that a friend of his who is a member of the British Medical Association proposes to put on the market a proprietary medicine which will be advertised under a fictitious name from an address several miles distance from where he lives and practises, all traces of his connexion with it being kept concealed as far as possible. We are asked whether, if the facts become known, he will be liable to have his name removed from the *Medical Register*.

"* The General Medical Council has published no warning upon this subject, nor, so far as we know, has it ever had to express an opinion on such a case, but the rules of many of the licensing bodies prohibit the holders of their diplomas from having any interest in the sale of any secret remedy. We do not doubt that any one acting in the manner described by our correspondent would expose himself to the censure of any medical authority before which his conduct might be brought, and would either have to sever his connexion with the proprietary medicine, or be deprived of his diploma.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

The following degrees were conferred on March 6th:

M.D.—J. C. W. Graham, Trin.; H. B. McCaskie, Gonv. and Cai.
M.C.—T. H. Kellock, Emms.
M.B.—R. L. Ley, Pemb.; R. A. P. Hill, Gonv. and Cai.
B.C.—J. C. W. Graham, Trin.; R. M. Vick, Jes.

It has been decided, on the recommendation of the Special Board for Medicine, that a Certificate of Practical Instruction in the Administration of Anaesthetics will be required for the Third M.B. Examination, Part II, in December, 1909, but this regulation will not apply to students who have passed the Second M.B. Examination on or before December, 1908.

UNIVERSITY OF LONDON.

UNIVERSITY COLLEGE.

The Annual Report.

THE annual report for the year ending February, 1909, has been issued; the total number of students was 1,361, an increase of 170. In the Faculty of Medical Sciences there were 183 students.

Buildings.—Rapid progress has been made in the new buildings for the department of physiology; the bequest of £5,000 by the late Thomas Webb, of London and Cardiff, has been devoted to its completion and fitting. A special appeal is made for £70,000 for new buildings for the department of chemistry.

Research.—The organization of the arrangements for post-graduate courses and for research has been improved, and the number of such students has increased from 171 to 239.

Libraries.—The rearrangement of the libraries in consequence of the increased space available has made rapid progress, and the card catalogues are nearly complete; 3,580 volumes have been added during the year, of which 2,600 were bequests or gifts.

UNIVERSITY OF EDINBURGH.

UNIVERSITY COURT.

AT the February meeting of the Court the following additional examiners were appointed: Dr. John Gibson, Edinburgh (Chemistry); Dr. George Lovell Gulland (Practice of Medicine); Mr. William A. Brend, M.A., M.B., B.Sc., London (Forensic Medicine); Dr. A. Wallace Williamson, Medical Officer of Health for the City of Edinburgh (Public Health); Professor A. R. Cushny (London) and Lieutenant-Colonel Firth (Army

Medical Department) were appointed additional examiners in connexion with theses submitted for the degree of D.Sc. On the recommendation of the Senate it was agreed to recognize the Public Health Laboratory of the University of Liverpool for purposes of graduation in Science in the Department of Public Health.

On the recommendation of the Senate the Court granted leave of absence to Professor Chien on account of the state of his health, and approved of the arrangements which had been made for the discharge of the professor's duties during his absence.

Dr. Alexander James and Dr. Claude B. Ker were appointed University Lecturers on Infectious Fevers.

The Services.

ROYAL NAVY MEDICAL SERVICE.

THE GILBERT BLANE MEDAL.

THE gold medal founded by the late Sir Gilbert Blane, Bart., to be given biennially, has been awarded by the Medical Director-General of the Navy and the Presidents of the Royal College of Physicians and the Royal College of Surgeons to Staff Surgeon Charles R. Nicholson, for his Journal of H.M.S. *Egmont*, November 6th, 1906, to December 31st, 1907; and to Staff Surgeon Arthur W. B. Livesay, M.B., for his Journal of H.M.S. *Bonaventure*, April 2nd to December 31st, 1907.

ROYAL ARMY MEDICAL CORPS (TERRITORIAL).

FIELD AMBULANCES.

IN the note published in the JOURNAL of February 27th p. 564, it was said that we believed that the 3rd South Midland Field Ambulance was the first in the kingdom other than a cavalry field ambulance to obtain its full establishment of men. Lieutenant-Colonel H. G. Falkner, commanding the 3rd Northumbrian Field Ambulance, informs us that that ambulance having its head quarters in Hull has been full for some considerable time; on March 1st it had 224 men, and 8 officers, and 11 special reserve, making a total of 243. He adds: "We have laboured under the same disadvantages as the 3rd South Midland Field Ambulance, for we have no head quarters, some men having to be drilled in one part of the town, some in another; we have no wagons, nor harness, nor means of teaching the men their proper drill. We have also had the special mark of approval by being granted the permission to wear gold ornaments. I hope before long to be able to fill the two vacancies for officers."

SECOND LONDON DIVISION.

THERE are vacancies for officers in the second London Division, which the Administrative Medical Officer desires to fill up at an early date. The vacancies include two in No. 4 field ambulance, head quarters at Woolwich, three in No. 5 at Greenwich, three in No. 6 in London, three in the sanitary company, one in No. 3 general hospital, besides fourteen vacancies in the infantry battalions situated in various parts of the County of London, and six in the Artillery and Engineers. Full information may be obtained by application to the Administrative Medical Officer, Craig's Court House, Whitehall, S.W.

EXAMINATION FOR PROMOTION.

INSULA asks (1) what books to read for the promotion examination from Lieutenant to Captain in the R.A.M.C. Territorial, (2) whether there is any place that he could attend a course of practical instruction for the above, and (3) whether the R.A.M.C. (Territorial) has been granted the right to wear gilt ornaments.

"* (1) Our correspondent should purchase a copy of *The Regulations of the Territorial Force and for County Associations* (London: Wyman and Son, 9d.), where he will find particulars as to the examination for promotion. Books to read are *Royal Army Medical Corps Training, Manual of Sanitation in Its Application to Military Life* (2d.), *Regulations of the Army Medical Service* (6d.), *Regulations for Recruiting*, to be obtained through any bookseller or direct from Messrs. Wyman and Sons, Fetter Lane, E.C. (2) There is a Territorial school in each division where courses of instruction are given from time to time. An officer desiring to attend should put himself in communication with the Administrative Medical Officer of the division he resides in. (3) The R.A.M.C. (Territorial Force) as such has not been granted permission to wear gold instead of silver, but permission has been granted to a good many of the units which have asked for it.

Obituary.

THOMAS WAKLEY, L.R.C.P.LOND.,

EDITOR OF THE "LANCET."

THE death occurred, at his residence in Hyde Park Gate, on Friday last, March 5th, of Thomas Wakley, part Proprietor and Editor of the *Lancet*, and although it was widely known that he was in bad health, the fatal termination of his illness has come as a shock to his many friends, among whom we count ourselves.

Thomas Wakley was born on July 10th, 1851, and was therefore only 57 when he died, an age at which nowadays a man counts upon at the least one more decade of active work. He was the only son of the late Thomas Henry Wakley, who between the periods of 1837 and 1907 was the senior Proprietor and Editor of the *Lancet*, and throughout his father's life worked hand-in-hand with him in the conduct of that journal. Thomas Wakley was educated at Westminster School and Trinity College, Cambridge. At school he took a high position in his classes, as is shown by the fact that he was chosen for a part one year in the famous Westminster play, and he obtained a leaving scholarship on entering the University. He also represented Westminster both at cricket and football, and won the quarter-mile.

He entered the University with the intention of joining the medical profession, the further object being to follow in the footsteps of his grandfather and uncle, and devote himself to the conduct of the *Lancet*. He proceeded no further in the medical curriculum at Cambridge than the passing of the First M.B., and at this period of his life probably contemplated some other future. A serious fall from a bicycle compelled him, however, to relinquish all courses of study for some years. He was thrown violently from an old-fashioned high machine on to his temple, sustaining what was possibly from the symptoms some slight fracture of the base of the skull. For some days his life was in danger, but eventually a slow recovery of health was established, although he never recovered complete sight in his right eye.

The resolve to enter the medical profession, and to join his uncle, Dr. James Wakley, in the conduct of the *Lancet*, now returned; and he entered as a medical student at St. Thomas's Hospital, obtaining in 1883 the diploma of L.R.C.P. Immediately afterwards he entered the office of the *Lancet* to begin the working life of a journalist under the eye of his uncle and of Mr. H. A. Beckett, Dr. Wakley's competent assistant. He was thus enabled to get the benefit of three years' routine work under two thoroughly experienced medical journalists, and under also the eye of an informal sort of committee of reference who assisted Dr. James Wakley in the conduct of the *Lancet*, among whom may be mentioned Surgeon-General

Marston, C.B., Sir John Tweedy, and the late Dr. James Grey Glover. Dr. James Wakley during the last two years of his life was afflicted with a malignant disease of the tongue, and in September, 1886, he succumbed to his fatal malady, and the editorship of the *Lancet* passed to his elder brother, the late Mr. Thomas Henry Wakley, and to his son, the deceased. For over twenty years, therefore, father and son co-operated in the conduct of a paper founded by the father's father more than sixty years earlier, figures which constitute, we should think, a record in heredity applied to journalism.

It would not be exactly our province to estimate Thomas Wakley's career as a journalist further than to say that he worthily maintained the honourable traditions of the great journal whose fortunes he was called upon to direct. But there was one side of his work to which we desire emphatically to bear testimony. The fairness of mind for which he was so well known among

his friends led him into relations with ourselves of a particularly pleasant sort. As a result both journals came to recognize that while keen rivalry was the best incentive to enterprise, such rivalry in no way precluded the existence of cordial good feeling between those responsible for the two journals. He was a man who by speech and manner inspired absolute confidence in his straightforwardness, and longer experience only proved that this was the root quality in his character. His word was his bond, and he was constitutionally incapable of a mean action. He had a high ideal of the obligations of medical journalism, and of the services which it was capable of rendering to the profession in this age. When the International Association of the Medical Press was formed he took a warm interest in it, undertook the duties of Chairman of the National Committee, and on the two occasions on which the International Committee met in London he extended to the members (on the first occasion in asso-

THOMAS WAKLEY.

ciation with his father) most generous hospitality.

In private life Thomas Wakley was a very quiet and retiring man, and, although by a few intimate friends his excellent personal qualities were well recognized, in anything like society at large he was comparatively unknown. Few men, indeed, ever held so public a position to use it with so little attempt at self-advertisement or self-advancement. He rarely took long holidays, and when he did he seldom went further than to some riverside resort, generally somewhere on the Thames. He was particularly attached to the Thames, and in 1896 wrote an amusing booklet recording four or five trips taken with his cousin, Mr. Frank L. Playford, the famous sculler, in their boat. *The Log of the Wyvern* was only privately printed, but it forms an interesting record of several quiet holidays of a kind that are no longer quite possible.

Thomas Wakley was an enthusiastic Freemason, was the recipient of several Grand Lodge Honours, and a generous supporter of the Masonic charities. He also was

a keen numismatist, a Fellow of the Royal Numismatic Society, and the possessor of a valuable collection of coins to which he made regular and constant additions.

Wakley lived until middle age as a bachelor in his father's house, but in 1903, to the great pleasure of his friends, he entered upon married life. He married Gladys, daughter of the late Mr. Norman Baron, by whom he leaves one son.

The body was cremated at Golders Green on March 9th; the funeral service, held at St. Mary Abbots, Kensington, on March 10th, was attended by, among others, Sir Constantine Holman, Sir Shirley Murphy, Dr. J. F. W. Tatham, Dr. David Nicholson, C.B., Surgeon-General Marston, C.B., Surgeon-General H. Skey Muir, C.B., Dr. Danford Thomas, Dr. Buzzard, Mr. Edmund Owen and Mr. Guy Elliston, representing the British Medical Association, and Dr. Dawson Williams, Editor of the BRITISH MEDICAL JOURNAL. The interment at Putney Vale Cemetery was attended by the personal friends of the family.

The cause of death was a gradually progressive toxic anæmia.

SIR JOHN WATT
REID, K.C.B., M.D.,

FORMERLY DIRECTOR-
GENERAL, R.N.

By the death from pneumonia, which occurred in London on February 24th, of Sir John Watt Reid, the navy loses a man who was prominent in its medical service during the latter half of the last century.

Born in May, 1823, he was in his 86th year at the time of his death, and had retired from active service since 1888.

He received his medical education in Edinburgh, and took the diploma of L.R.C.S. in 1844, and graduated later at Aberdeen. Entering the navy in 1845, he served as Assistant Surgeon on the Mediterranean and North American Stations. As a Surgeon he again served on the Mediterranean Station during the war with Russia in 1854-5 in H.M. ships *Inflexible* and *London*, being stationed in the Black Sea until the fall of Sebastopol. For these services he received the Crimean medal with clasp and the Turkish medal. From 1857 to 1859 he served in China on board the hospital ship *Belleisle* during the war, and received the China medal.

From 1860 to 1864 he again served on the North American Station, and in 1861 received an expression of their Lordships' satisfaction at his zeal and attention to duties during a severe visitation of yellow fever at Halifax. As a Staff Surgeon, in 1874, he was employed on board the hospital ship *Nebraska* during the Ashanti campaign. He was mentioned in dispatches, received the medal, and was promoted to Deputy Inspector-General for his services. As Deputy Inspector-General he was employed at Bermuda and Haslar Hospitals. In February, 1880, he was selected for the appointment of Medical Director-General of the Navy, his promotion to Inspector-General being made at the same time. Almost immediately after his appointment—March 5th, 1880—a Committee on the Medical Officers of the Navy was appointed, with Rear

Admiral A. H. Hoskins as President and Sir John Reid as one of its members. His tenure of office as Medical Director-General was marked by the abolition of Netley Hospital for the instruction of naval medical officers on entry and the institution of a course of instruction at Haslar Hospital, the introduction of the payment of gratuities to officers wishing to withdraw after short service, and the first appointment of nursing sisters to naval hospitals.

He was appointed Honorary Physician to Queen Victoria in 1881, and on her death in 1901 he was made Honorary Physician to the King. He was created K.C.B. in November, 1882; in 1884 the honorary degree of LL.D. was conferred upon him by the University of Edinburgh; and shortly after his retirement he received a Good Service pension of £100 a year.

All who came in contact with him were struck by his genial manner and kind-heartedness; he was well known to and welcomed by all branches of the navy, and by his many acts of kindness helped to popularize the Naval Medical Service, with which he had so long and honourable a connexion.

JOSEPH HENRY
IRVIN,

M.R.C.S. ENG., L.R.C.P.I.
F.R.S. MEDICAL OFFICER,
ROYAL LANCASTER
INFIRMARY.

To the deepest sorrow of all his professional brethren, and every one, rich and poor alike, in the town and district around Lancaster, Joseph Henry Irvin passed away after a few days' illness on February 13th, in his 54th year. He was the second son of the late Mr. David Irvin, J.P., of Preston. He received his professional education first at the Manchester Infirmary, and afterwards at St. Mary's Hospital; took the diploma of L.R.C.P.I. in 1878, and that of M.R.C.S. Eng. in 1880. In 1880 he settled in Lancaster, and soon after joined Dr. William Hall in the partnership which lasted until his death.

His professional ability was of the highest order, his surgical knowledge such that his opinion was sought for and valued in the highest degree by every one of his colleagues in the district, and his manipulative skill and resource in moments of emergency were undoubted.

In February, 1882, he was elected an Honorary Medical Officer of the Lancaster Infirmary, now the Royal Lancaster Infirmary, and this office, together with that of Governor of the institution, he retained up to the time of his death. He was a strenuous worker, and to his younger brethren of the staff he was a tower of strength. He had an individuality of his own, only known to his intimate friends, and his place in the hearts of his colleagues in the Infirmary and in the town can never be filled. During his student days he was a resident pupil for most of his time in the Royal Infirmary, Manchester, and he there acquired that excellent grasp of surgical emergencies which bore such good fruit in later life. There he met many men who have since made their mark in the profession, and whose close

friendship he retained until the day of his death. The following extract from the *Times* some time in September, 1876, shows the plucky and unselfish side of his character; it describes an incident in his life known to very few, for his modesty in all things connected with himself was great.

HEROISM.—The Rector of Cheddle, Cheshire, writes to us: "Can you find space to record an unostentatious act of heroism? A poor factory operative had his leg recently amputated in the Manchester Infirmary. The loss of blood was so great that his case was given up as hopeless. He was all but dead, when the surgeon stated that nothing but an infusion of blood could save his life. One of the students (a Mr. Irvin, I believe) volunteered to be bled, and 25 oz. of his life blood were taken from him at his own most serious risk and infused into the dying man. Yesterday I saw the patient, who is now on a fair way to convalescence. Need we wonder that the noble band of English doctors on the battlefields in Turkey should reflect such credit upon their country?"

Transfusion in 1876 was a very different matter from the saline injection of the present day, and his volunteering at a moment's notice to perform an act whereby he knew his life might be placed in jeopardy (as it actually was for many weeks afterwards) proved that he was worthy of the best traditions of our profession.

Dr. Irvin was a good sportsman—a first-rate shot and a keen golfer; in his earlier life he was an excellent swimmer, and did much to encourage and extend a knowledge of this art among the boys and girls of the town. Good music was especially dear to him, and he was himself an excellent musician. He was an enthusiastic Freemason, and his presence at the meetings of his lodge was always a source of pleasure to the members of the craft.

For some eight years he was Acting Surgeon to the 1st Volunteer Battalion Royal Lancaster Regiment, but resigned his appointment in June, 1889.

Dr. Irvin leaves a widow and one son and daughter.

He was buried in Lancaster Cemetery on February 16th; the funeral was one of the largest and most representative ever seen in Lancaster. Every medical man for miles around attended and thus paid a last tribute of respect to the "straightest man in the profession," while all classes of society from the highest to the lowest showed by their presence the love they bore him.

ROBERT POLLOK, M.B., F.F.P.S.GLASG.,

PHYSICIAN, SAMARITAN HOSPITAL FOR WOMEN, GLASGOW.

His death took place on February 11th of Dr. Robert Pollok of Pollokshields, Glasgow, occurring quite suddenly, in the 54th year of his age. He was born at Tarbolton, received his early education in that locality and completed it at Ayr, whence he passed on to Glasgow University and graduated M.B., C.M., in 1876; some years later he received the diploma of F.F.P.S.Glasg. Meanwhile he visited various places of medical study on the Continent, and finally equipped himself for private practice by acting as assistant to various medical men of standing in the West of Scotland. Among these was the late Professor James Morton of Anderson's College, and it was owing, perhaps, to this circumstance that Dr. Pollok eventually joined the staff of the dispensary of Anderson's College. In Glasgow he soon established both a sound practice and an excellent reputation with the public and his professional colleagues. His work in connexion with Anderson's College he carried on up to the time of his regretted and untimely death, another appointment held by him being that of Physician to the Samaritan Hospital for Women. Dr. Pollok found vent for his activities in many directions, but professionally it was the subject of obstetrics, perhaps, for which he showed the strongest predilection. Some excellent contributions to the current literature of this subject came from his pen. Amongst them was one on 2,000 cases of delivery in private practice, dealing with the difficulties encountered and the fashion in which they were met. In another he considered abortion, its avoidance, and its treatment. He was a man, however, of far more than one intellectual bent. The Philosophical Society and the Natural History Society both owned him as a member, and he played, likewise, an active part in the affairs and debates of the Glasgow Obstetrical and Gynaecological Society and the Glasgow Southern Medical Society. Each of

these in turn did him the honour of electing him to the Presidential Chair. He was also medical referee to insurance societies, while outside purely professional and scientific occupations he took a great interest in the medical work of the auxiliary forces. Joining the Blythswood Rifles early in his career he evidenced his keenness in this connexion by volunteering to proceed to South Africa early in 1900. There he saw a great deal of service both at base hospitals and with moving columns, and returned with the Queen's medal and three clasps—including one for the hard fought action at Belfast—and an honorary Captaincy in the army. When the Territorial Force was instituted he showed the same patriotic interest in its success, and at the time of his death had not long been gazetted in charge of the 4th Scottish Hospital under the Territorial scheme. A man of such mental and physical activity and excellent professional and social qualities naturally attracted great esteem, and his death leaves a gap which will not rapidly be filled.

DR. JOHN MACDONALD MACLENNAN died suddenly in Glasgow on February 23rd. He graduated in Arts at the University of Edinburgh, and followed this up by taking the M.B. and C.M. degree in 1885. Owing to ill health he was never able to undertake the duties of private practice, and for several years he acted as Surgeon on board Allan, Castle, Clan, and other liners. His experiences in many parts of the world were varied and thrilling. He was shipwrecked off the coast of Chili and again at the mouth of the Ganges. Dr. MacLennan was possessed of a genial and kindly disposition, and made many friends wherever he went. He bore the misfortune of prolonged ill health with great fortitude, but of late years he became so seriously ill that he had to give up all work. He retired to Kingsley about three years ago; he subsequently went to Glasgow for further medical treatment, and remained there until the time of his death. Dr. MacLennan was unmarried.

THE death of Dr. EASTON, on March 4th, is a matter of deep sorrow and sincere regret to a large circle of personal friends as well as to those who were associated with him in his many public activities. Thomas Easton, the son of the Rev. Matthew George Easton, was born in 1859 at Girvan Manse. In 1862 the family migrated to Darvel in Ayrshire, where the most important part of Rev. M. G. Easton's work was done and where now in memory of his pastorate the Easton Memorial Church stands. Thomas Easton received his earliest education from his father and at the village school; later he was placed at the Ayr Academy, where he obtained an excellent classical training. From there, in due course, he proceeded to Edinburgh University, graduating M.A., and subsequently M.B. (1884). Before commencing practice he studied in Berlin and acquired an excellent knowledge of the German language, which proved valuable to him through the later portion of his life. On his return to England he spent some time in St. Thomas's Hospital, London, and in 1886 graduated M.D. Edin., his thesis on manual treatment of diseases being commended. After acting for some time as an assistant in London he succeeded to the practice of his uncle, Dr. David Easton, of Stranraer, in Wigtonshire, where he remained until 1899, living a life of strenuous and unremitting toil. He held many public appointments in connexion with the workhouse, the lighthouse, the reformatory, etc.; he was Medical Officer for the parish of Leswalt, and became a J.P. for the county. The strain of work caused a breakdown in health, and he resigned his many offices in Stranraer, seeking the much needed recreation and rest in Continental travel. The change was speedily beneficial, and Dr. Easton settled in practice in Southampton; he was appointed a Medical Officer to the Poor Law, and was elected to the Borough Council. He became a member of the Education Committee of the borough, and for a time was Chairman of the Higher Education Subcommittee. He was also a member of the Endowed School Governors and of the Council of the Hartley University College. All useful educational movements received his sympathy and support; he was one of the original members of the Southampton Record Society and of the Historical Association. His death at the early age of 49 is deeply deplored and much sympathy is felt with his widow and one daughter.

Letters, Notes, and Answers.

BRITISH MEDICAL ASSOCIATION AND BRITISH MEDICAL JOURNAL
THE offices of the British Medical Association and of the
BRITISH MEDICAL JOURNAL are at 429, Strand, London.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

NEURASTHENIC ASTHENOPHIA.

Oculus asks for advice in the treatment of a case of neurasthenic asthenopia in a young man whose general condition is now practically normal, who is free from organic disease, and who leads a hygienic life. Errors of refraction have been corrected by an ophthalmic surgeon, and there is no doubt the appropriate correction has been arrived at. On some days he can read or write for several hours without distress, on others, after using his eyes for half an hour, an aching and strained feeling comes on, chiefly referred to the eyeball itself, which makes it impossible to continue. The position of his desk has been considered, as have also the nature and direction of the light by which he reads. Is there any form of eye massage or douche which could be applied?

ANSWERS.

HOSPITAL FLOORS.

DR. JNO. MILSON RHODES (Didsbury) writes: "B. G. M." will find Parian cement the best for filling up the cracks in the hospital floor, failing that, the next best is Portland cement.

A CASE FOR DIAGNOSIS.

A. S. M. writes in reply to "B. S." to suggest that the case should be regarded as one of dilatation of the stomach, and that it be treated by lavage, and phenol in pill form after food.

TREATMENT OF BRONCHIAL ASTHMA.

A. S. M. writes in reply to the query in issue of January 30th, re treatment of bronchial asthma, to suggest for trial the tincture of lobelia and glycerine (equal parts) in an Oppenheimer's Aerizer.

INCOME TAX.

C. E. A. A.—If the surveyor agreed with our correspondent to allow payment of the tax for the year 1908-9 to stand over until he should be in a position to render an account of his profits from May 1st, 1908, to April 30th, 1909, there is no reason why this arrangement should not be adhered to. In that case C. E. A. A. would not be required to send in his next return until after April 30th, 1909, and if he receives an earlier application for a return he should, for his own protection, draw the attention of the surveyor to the arrangement stated to have been made. Moreover, if the surveyor made such an arrangement, he is scarcely likely to insist now on payment of the original demand. No point of law appears to be involved, and our correspondent does not give any reason for supposing that the arrangement made will not be carried out by the surveyor.

BOYS' SCHOOLS IN FRANCE.

SOME weeks ago an inquiry was inserted from a correspondent who wished to hear of a school or tutor in France for a boy of 10, where he could receive a good English education and at the same time learn to speak French fluently. Several replies were received and their substance communicated to the inquirer, but it is suggested that the information may be of use to other parents. **Dr. A. P. Trinder** (Bembridge, Isle of Wight), and **Dr. W. Pitt Palmer, D.P.H.** (Babbacombe, Torquay), both recommend a school kept by the Rev. E. Owen Burbridge, B.A. Lond., 19, Route de la Hève, Sainte Adresse, Seine Inférieure, France. Sainte Adresse is a suburb of Havre, and there is sea-bathing in addition to hockey, football, and a gymnasium. Both Dr. Trinder and Dr. Palmer before putting their sons to this school inspected it with special reference to sanitary arrangements, both speak well of the surroundings of the house, and Dr. Trinder can guarantee the sanitation and water supply, the latter being, he says, one of the best in France. **Dr. O. Trafford Owen** (Blackburn) recommends a school information as to which can be obtained from Dr. Philip, 95, Grande Rue, Boulogne-sur-Mer.

LETTERS, NOTES, ETC.

SOUTHWOLD LIBEL CASE.

THE following additional subscriptions have been received by the fund opened to assist Drs. Mallock and Tripp in defraying the heavy expenses which they incurred as the result of the recent action which they were called upon to defend:

	£	s.	d.
Sir Victor Horsley, London	...	5	0
Dr. W. E. Baylie, Yorkford	...	3	0
Dr. W. M. Crowfoot, Beccles	...	2	0

Cheques should be made payable to Dr. H. P. Helsham, Beccles, or to Dr. W. Tyson, Lowestoft.

ACTION OF RADIUM ON CORNS.

DR. RALPH BROWNE-CARTLIEW (London, S.W.) writes: Some of your readers may be interested with regard to radium, that amongst its humbler possibilities is its power to remove corns. In this it is very effective, and gives a simple demonstration of its power of action where there is irritation and proliferation of epithelial cells.

A PROTEST AND AN EXPLANATION.

DR. H. SELFE BENNETT (London, W.) writes stating that he is informed that many members of the profession and the general public, friends of his and utter strangers alike, have recently received a type-written letter dated from his address and marked "Private, personal, and without prejudice," ending with a sentence which reads as follows: "I am happy to think that though I have come across many rascals in my time, you are still an exceptional specimen of humanity in the experience of (Sd.) H. Selfe Bennett." Dr. Bennett informs us that the letter thus purported to be reproduced was written six months ago to the defendant in a nullity suit in which he gave evidence. He desires it to be understood that the communication has been sent to the numerous persons who have received it without his knowledge or sanction, and that he is taking legal advice on the subject.

ANTIVIVISECTION AND THE POOR.

HIRUDO writes: In a leaderette in the JOURNAL of February 20th you quote with approval the remark by Dr. Mande that Henry Hunt was "a prototype of many Radical politicians of to-day who are fond of expressing very decided opinions on scientific questions of which they have little knowledge." May I venture very respectfully to suggest that the omission of the word "Radical" would not spoil the observation, and would be more in keeping with the supposed non-partisan character of the JOURNAL?

"* We in turn would venture "very respectfully to suggest" that there is no partisanship in the statement of a notorious fact. It is not a question of political opinion, but of temper of mind. Independence of thought exercised within its proper sphere makes directly or indirectly for progress; but in scientific questions the "great heart of the people" can scarcely be taken as a trustworthy guide.

HOSPITAL FOOTBALL.

FOOTBALL during practically the whole of last week was impossible as, even in London, the grounds were several inches under snow. Last Tuesday, however, after nearly three weeks' delay, Middlesex Hospital replayed St. Thomas's at Richmond, and defeated them in a hotly contested game by one try to nothing. Curiously enough, despite the fact that on the last occasion when the two hospitals met there was a keenly disputed if rather unscientific match, there was a very poor attendance. The ground was in terrible condition owing to the weather, and after the first few minutes of the game rendered anything like accurate football impossible. The hospital style is notoriously a game for the forwards, and this feature, thanks to the condition of the ground, was specially marked. The inevitable scrambling game resulted, one pack or other breaking through and dribbling the ball along until some one by a lucky kick managed to find touch. Despite these adverse conditions the superior qualities of the Middlesex backs told, for though St. Thomas's usually had the better of the forward game, the Middlesex halves again and again saved the situation by their smart tackling and their clever kicking into touch. Whenever they were able to pick up the ball and managed to start a run, their superior pace made itself felt, and in their combination they proved very much more than a match for the St. Thomas's men. During the whole of the first half the play was up and down the field, neither side showing itself markedly superior, and it seemed as if another draw would have to be declared. With the beginning of the second half, however, play was much livelier and brighter, and the two fifteens abandoned the defensive attitude adopted in the first half and a more open and a faster game was played. Middlesex succeeded in pressing St. Thomas's back, and O'Kane cleverly took advantage of an opening, slipped over the line and scored his try. Harrison took the kick but failed to convert, and time was called without there being any further scoring. For the winners Penny and Saunders were especially conspicuous, while St. Thomas's owed most to Warburton and Nicholson. As a result Middlesex enters the final round and it has been arranged that the match with Guy's shall be played on Tuesday next at Richmond.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Eight lines and under	...	0	0
Each additional line	...	0	6
A whole column	...	2	13
A page	...	8	0

An average line contains six words.
All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication; and, if not paid for at the time, should be accompanied by a reference.

N.B.—It is against the rules of the Post Office to receive letters at *Postes Restantes* addressed either in initials or numbers.

An Address

SOME INSUFFICIENTLY RECOGNIZED POINTS IN THE DIAGNOSIS OF DISEASE.

DELIVERED BEFORE THE EAST YORKSHIRE DIVISION OF THE
BRITISH MEDICAL ASSOCIATION AT HULL.

SIR DYCE DUCKWORTH, M.D., LL.D., F.R.C.P.

CONSULTING PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL; SENIOR
PHYSICIAN TO THE SEAMEN'S HOSPITAL, GREENWICH.

GENTLEMEN,—The title of this address may not improbably excite some wonder in the minds of my audience. It may appear to be a bold step to assert in these days, even tentatively, that there still remain any points which elude or fail to receive full consideration in matters relating to diagnosis. It is now a mere platitude to speak of the extraordinary progress that has been made in the science and the art of medicine in the course of the last fifty years, for this is recognized on all hands, and we know well that fresh fields of research are being opened up daily by skilled and assiduous cultivators. So much so is this the case that it has become well-nigh an impossible task for the hospital teacher or the most diligent practitioner to follow up and utilize the products of these investigators. Never in the history of medicine was the first aphorism of Hippocrates borne in upon us with greater weight and solemnity than in this twentieth century, and we may well ask ourselves, Who, indeed, is sufficient for these things? To illustrate my statement, I will only ask you to compare the classical treatise of Watson—which was the textbook in medicine of most of the greybeards now in our profession—with the outgoing new edition of Allbutt's *System of Medicine*, for this provides us at once with a standard wherewith to measure the progress that has been attained in our day. It is, indeed, startling and amazing, and I venture to think that no such advance can be placed to the credit of any other learned profession. I grant at once that the engineer, the electrician, and the astronomer may point to remarkable progress; but, if we regard the relation of their splendid efforts to the general welfare of our common humanity, I am bold enough to declare that our progress is distinctly the greater and more important.

Notwithstanding this notable advance in our knowledge, we appear to have arrived at a curious stage as regards medical doctrines at the present time. We hear it widely affirmed that our old medical and surgical books are now effete, and rather misleading than helpful. We witness a spreading wave of incredulity as to the virtues and value of many therapeutic measures which were practised and commended by our predecessors. We are inclined to ignore the preparations of our *Pharmacopoeias* and to employ the latest products of synthesis and many extraordinary combinations of food and medicines for our patients.

We lend a willing ear to the last declarations of the laboratory experts, and proceed to adopt their suggestions. I suppose this has to be to some extent, but I greatly fear that in such proceedings we run the risk of crowding out a good deal of soundly acquired and proved experience—it, indeed, this has ever been acquired—and of becoming medical scientists rather than expert medical practitioners.

Let me not be misunderstood. I am in no degree averse from the best and most necessary researches of all our laboratories. These must be prosecuted, and especially those which are carried on in clinical laboratories, of which we still have too few in our great medical schools in this country; but I maintain that in the best interests of our patients there are limits to the too ready employment of such measures as are now month by month foisted on our attention. Let us consider what is the meaning of experience in our profession. What is it that we call for, and fall back upon, in any grave crisis in our clinical work? Is it not the opinion formed by the man who has seen much of disease, who has watched it and pondered over it, and best conducted his patients through their maladies?

Is it in such crises that we instinctively appeal to the last experiences of the laboratory operator? Some of you will doubtless reply to me in the affirmative, and tell me of the hopelessness of treating diphtheria, tetanus, anthrax, and other toxic invasions on any other basis than that of the assured benefits derived from the laboratory, and, if so, I am entirely with you. And if you have come to regard all disease as the result of microbic or otherwise toxic intrusion into the body, your pathogeny is at once simplified, and you are henceforth the slaves of the laboratory, and have become administrators of serums and antivaccines. Well, gentlemen, I, for one, am not yet prepared to declare myself a convert to such extreme views. A long clinical experience bids me to keep my head clear, if I can, in these days (and it is no easy task), and to see all things medical with a *mens sana* and a *mens medica*. I have found that a large part of our best art is still founded on empiricism, and that we cannot give reasons for our practice which will satisfy the purely scientific mind. In daily practice, for the best interests of my patients, I am content to be a medical artist rather than a medical scientist, but I am ever ready to avail myself of the best science that comes to me with the approval of careful experience.

If we are to wait for a scientific explanation of every step we are compelled to take in our daily work, I much fear that our patients will also have long to wait for relief, and that we too shall have long to wait for reputation. This is, indeed, one of the great difficulties that beset us. It renders it hard, and in some cases an impossibility, for certain men in our profession to practise efficiently. They cannot rest content with mere empiricism; they want a scientific reason to justify every dose of medicine and to support every method they employ. Not finding it, they leave our ranks, and are tempted to scoff at our efforts as mediaeval, tentative, and uncertain. This is a clear indication, as I venture to think, of the absence in these men of the *mens medica*. No, gentlemen, the best practice of medicine is not yet altogether scientific, and if we are to help our patients, we must for the present do what carefully acquired experience justifies us in doing. Our art is, indeed, based upon many sciences, but it is not yet scientific. It is certainly becoming more so year by year, as we gratefully acknowledge. In the meantime we have carefully to cultivate the art of medicine, taking advantage gradually of every scientific fact which is of proved utility.

These considerations, preliminary indeed, bring me now to the topic on which I desire to speak this evening, namely, to urge the importance of a study of the patient no less than a study of his disease. I am strongly impressed with the belief that there is a tendency at present to pay rather too exclusive attention to the pathological process which is in progress, and to neglect the peculiarities of the individual and the conduct of his particular constitution in relation to the particular illness. In the case of a manifest toxic invasion, I think we are now rather too apt to be engrossed with the *microbe* and its delinquencies, and to forget the equally important matter of the *soil* in which these work out their mischief.

We are disposed to regard the soil, or tissues, of the patient as an indifferent medium, akin to the agar-agar of the laboratory, equally ready to react and encourage the development of such processes as may be expected to follow on inoculation. A little consideration of the matter plainly corrects this view, and clinical experience proves that the soil is commonly as much concerned in the process as is the seed. The personal factor in disease has always to be reckoned with at the bedside, and from the nature of the inquiry here this point cannot be solved in the pathological laboratory. This constitutes, indeed, one of our great difficulties in experimentation. I would illustrate this very simply by taking the case of the transmission of bovine tuberculosis to the human subject. As you are aware, there is a preponderance of scientific opinion to the effect that such transmission is not only possible but certain, in defiance of Professor Koch's strong view to the contrary. I am not aware that there are certain facts determined as to the direct infection by milk of tuberculous cows in the case of human subjects. We cannot deliberately administer obviously tuberculous milk to children to prove this, but we know that large quantities of such milk are daily partaken of by children and adults, since so many apparently healthy cows are found to be

good milkers, although obviously vulnerable to tuberculin when tested by it.

The experiment is thus being made for us in the homes of too many of our fellow-creatures, and if the results are not more serious than might be expected, we may explain the fact by assuming that there is often an inherited immunity which is protective, or by finding that the infection has been arrested in the mesenteric glands, and rendered inoperative for further development. Dr. Nathan Raw, of Liverpool, who has studied this question with much care, informs me that no actual proof exists of the production of tuberculosis in children, as no one has made the experiment of feeding with milk known to be tuberculous, but he believes that all the collected facts point in the direction that abdominal tuberculosis occurring in the milk-drinking period is due to infected milk, more especially as the bovine bacillus has been isolated from the mesenteric glands by both the British and German Commissions on Tuberculosis. He mentions further, that in those countries where raw milk is not taken, abdominal and milinary tuberculosis is practically unknown.

Professor Koch appears now to be wavering in his opinion. He agrees that bovine tuberculosis may be conveyed, but is not yet prepared to admit that pulmonary tuberculosis is produced by it. Our position, as clinicians, is quite clear in the matter for the present, and we must stand by the British view of the infection from a bovine source, and act accordingly, and without delay.

The personal or individual factor is probably different in the case of the lower animals as compared with the human subject, but in the former there are found to be differences of susceptibility, even in individuals of the same class.

Those who see much of family practice over long periods become aware of family and personal peculiarities which tend to modify the incidence and course of various diseases, many of which are not so manifest to those who, as Sir Andrew Clark used to say, "see sick people, but have no patients" in the ordinary sense. A knowledge of the antecedent history, both family and personal, is necessary to a full understanding of this matter, and this is not readily secured amongst the poorer classes. I think we often fail to make, or try to make, what is called a physiological diagnosis of our patient—that is, to judge promptly, by practice of it, as to the habit of body or diathesis of the individual. Here, again, we are apt to regard most individuals as alike in tissue proclivity and tendency, and to expect the varied processes of disease to act indiscriminately upon each of them. Yet we find that this is not the case, some reacting mildly and others gravely; a toxic dose being borne well and disposed of favourably in the one, and in the other rapidly proceeding to fulminant and death. Again, we meet with absolute immunity in certain individuals, a condition not yet fully explained. We note the greater liability to some diseases at certain developmental epochs, a matter of importance, not seldom, in difficult and puzzling cases. Thus, amongst those which present unusual symptoms in children and young adults, we may often find the explanation in tuberculosis; in adults up to middle life, many strange and untoward symptoms are found to be dependent on unrecognized syphilis; while, in the aged, we find that some of the most puzzling conditions are sometimes ultimately resolved by a sharp attack of acute gout. Let us consider next two of the commonest diathetic conditions we have to deal with—the scrofulous or strumous habit, and the arthritic, often called rheumatic, habit. The facies in each is sufficiently distinct; the former presents two main varieties, known respectively as the "ugly" and the "pretty" struma. The "ugly" variety is that commonly described in textbooks. Its characters are the full, big face, swollen neck, sallow complexion, tumid lips, with catarrhal manifestations. The "pretty" variety presents finely-cut features, with delicate complexion, fine hair, long eyelashes, and various qualities which clearly indicate both beauty and delicacy. These two types present us with features which are both vulnerable, and a ready prey to the onset and development of tuberculosis should infective intrusion occur. The "ugly" variety it was which first gave rise to the term "scrofula," from the full and short, porcine quality of the neck. Note, that neither of these may be called in the first instance tuberculous. They present a soil ever ready to lead to tuberculous infection.

The "ugly" variety, indeed, is a veritable forcing ground for every kind of vicious microbic intrusion, so that such individuals are the worst subjects for all infections, and have every ailment in a grave form. They succumb in early life to these, or manifest very indolent recuperative power. They rarely recover from nephritis, and in later life are the worst subjects of syphilis if smitten by it. This condition also modifies the course of many illnesses, and presents strange blends of morbid states when mixed infections occur. For instance, in the tropics, I am inclined to believe that such subjects are specially prone to suffer from hepatic abscess.

We now find these individuals described as tuberculous *ab initio*. This I regard as a grave error. They need never become tuberculous, although they are a ready prey for the infection. In the "pretty" variety, there is more particularly a tendency to mesenteric and pulmonary tuberculosis, and perhaps to articular disorders. I think we do not adequately recognize these facts at the present time. We may regard these subjects in respect of tuberculosis as the *ens in potentia*, and when definitely infected as presenting the *ens in actu*. The moral of it all is when detected as specifically vulnerable elements in a community to protect such subjects, even more than others, from tuberculous environment and infection.

Let us consider next the subjects of another habit of body—namely, the arthritic or so-called rheumatic. They present a peculiarity and delicacy of constitution very different from that of the scrofulous. We note in them an absence of the vulnerability of the lymphatic system which is so marked a feature in the subjects of struma. The facies does not suggest delicacy, there being neither timidity nor sallowness. There may be even in early life some vascularity of the face and a general good development. The tendency is to suffer from the various manifestations of rheumatic poison, whether developed in the throat, the skin, the heart, the joints, and the brain, especially during adolescence, the tendency to rheumatic infection passing off more or less after the third decade. Later in life some of these subjects become gouty, and are apt to suffer from myalgia, fibrositis, lumbago, sciatica, and neuritis, and many of them present examples of arterial sclerosis and contracting kidneys about the fifth decade. The physiognomy in the latter case is very different from that of the subjects of chronic parenchymatous nephritis. One of the most marked features of this diathesis is its resistance to tuberculous infection—a point little regarded. Even if tuberculosis is acquired it has a hard struggle to progress, and is either arrested or held in check for many years as a rule. It has been humorously asserted, indeed, that one way of avoiding tuberculosis is to grow gouty; and truly what is bad for gout is very good for tuberculosis—namely, full dietary, or what the French call forced alimentation. The prognosis in arthritic subjects, if no cardiac complications have occurred in early life, is good for longevity provided a suitable environment is secured, and if what Sir Andrew Clark termed "physiological righteousness" is observed.

I have been speaking of what may be regarded as pure specimens of these two habits of body; but, of course, we meet with many examples where there are blends of constitutions, intermixtures of diathesis, in which one condition may be more prominent than the other, yet potential for modification. Hence we find blends of struma and rheumatism, a bad conjunction; and blends of gout and struma, a rather less grave coalescence—less grave, I say, because the gouty element generally acts protectively, and permits of a better prognosis for longevity. Many of these arthritic subjects manifest a high arterial tension in middle life, and so, as Sir T. Clifford Allbutt suggests, we may be concerned for them should they fall victims to pneumonia, or, in later life, suffer from cerebral hæmorrhage. Such tendency, of course, puts us on our guard and demands attention to habits of life and diet. Yet another peculiarity pertains to arthritic subjects, and it is their singular susceptibility to the gonococcal virus. This infection is apt to be more serious in some than in others, especially in those of gouty proclivity, manifesting a special vulnerability in

I find that this point was quoted by W. Heberden at the end of the eighteenth century. "Struma et lues venerea nonnumquam eundem hominem simul occupant: quod ubi fit, altera alterius nocendi viam plurimum auget." *Commentarii de Morborum Historia et Curatione* (Cap. lxxvii, de Struma.)

their textures. In these subjects, too, we meet with Dupuytren's contraction and the curved little finger, known as "Landouzy's camptodactyly," which in my experience have no origin in purely rheumatic conditions. They are further liable to a hyperinotic state of the blood, whereby there is a special tendency to phlebitis and blood-clotting, a point to be remembered in the puerperal state in the case of gouty women, who are more than others liable to pulmonary arterial thrombosis. A due consideration of clinical facts such as these surely lends support to the doctrine of the diatheses which is at the present time too much discarded, and even denied and derided by some. I regard them as *fundamental* and amongst the certainties of medicine, and to disregard them is, I venture to think, an indication of the absence of clinical acumen in the disputant. This tendency to ignore the personal factor in diseased persons is probably to be attributed to our modern devotion to laboratory revelations, and our less assiduous observation in detail of the human patient actually before us. Being over-engrossed with the seed, we are neglecting the soil, and, as physicians, we have to take good heed to both in our daily duties.

There is much to be said in favour of a nervous or neurotic habit of body, where we find plain evidence of instability of nerve centres, with tendency to break down in various parts of the cerebro-spinal axis—a condition plainly inherited and transmissible, often blending with other diathetic proclivities. For an example, take the case of chorea, well termed "cerebral rheumatism." Here we have the distinct rheumatic infection, together with nervous erethism and instability. The rheumatic and choreic child is commonly the nervous child in a family, as pointed out by Cheadle. Other members may be infected, but they do not present vulnerable points in their cerebral cortex.

Neurotic disorders do not present gross textural change, but simply perverted nervous action. In the group of "family" diseases of the nervous system we find the inborn tendency to a breakdown of some nervous tracts, which may occur definitely in several members of a family, in one or successive generations, in early or late adolescence.¹

We may acknowledge a difficulty here, because we have in many cases no particular physiognomy to guide us in determining the subjects of neurotic tendency. We have, however, other features in abundance to observe, and especially the personal and family life-histories, so far as we can gather them, to throw light on individual cases. There may be a solitary case in a family, but antecedent histories may help us to find a clue to the particular infirmity which has cropped up.

Myxoedema and cretinism in an early stage may long remain unrecognized unless we are on the look-out for the peculiarities of the disease as disclosed by a change of physiognomy and of habits. The same may be said in regard to early phases of paralysis agitans before the onset of the tremors; thus, the mask-face, and the slow gait, with mental hebetude, may long precede the characteristic tremors, the piping voice, and the sweatings. If we pay too much heed to the disease, and neglect to study the patient, we may miss many indications of early phases of disease. Where a long report has to be made on a person under examination, say for a life assurance policy, it is possible to be so much engrossed in recording answers to questions that we fail to study the individual before us sufficiently, and so miss the fuller appreciation of the particular features of the case. Some of these insurance papers, especially the American ones, are so full of details that they are apt to lead to an inadequate appreciation of the examinee before us, and to occupy too much time.

The study of localized pain requires extreme care, and a minute series of inquiries and examinations which demands much time and thought if an exact diagnosis is to be made. A flippant diagnosis of "rheumatism," or "neuritis," or "indigestion," may be very wide of the facts before us, but we are expected to form an opinion with rapidity and certainty, and it may be a matter of days before we can trace a pain to its true source. The patient and his friends do not understand our proper hesitation and postponement of a satisfactory opinion on the case.

In cases of apparently simple anaemia, especially in males in middle life, we may sometimes discover the

reason of our inability to promote recovery by attending to the minute histology of the blood, and, finding an undue eosinophilic count of leucocytes, be led to the discovery of ankylostomiasis, which is perhaps more common than is generally believed, owing to the extended travels of our population at the present day.

The numerous varieties of skin diseases present us with a vast field for the study of constitutional states of body. They almost always bear on this question, and their removal commonly rests with a recognition of the particular personal habit, the strumous tendency to pus formation, the arthritic to serous effusion or scaling with pruritus, the bilious to xanthelasma, and the diabetic to vitiligoidea. Since the study of botany has been neglected in recent years in the medical curriculum, there has been, as I believe, a loss of discriminating power in our students, and less ability for accurate differentiation in common observation—a mental faculty greatly encouraged by early botanical study. The Edinburgh school has always recognized this, and insisted on its importance for the future physician, and, as I venture to think, with much benefit. Indeed, I believe that a little more botany and careful study of the *materia medica*, and a more assiduous observation of the action of some of our old approved remedies, would assuredly sharpen the clinical wits and acumen of our modern students and practitioners. Some measure of the over-elaborated studies in chemistry might well be curtailed to allow of this—certainly in the case of the average pupil, who has soon to make his way in general practice.

In my clinical teaching I have sometimes said to my pupils that there are almost certainly things that we are looking at to-day in our patients which, as yet, we do not see. Yes, looking at, without seeing, things which some one will some day see and recognize, and will wonder how we in our day failed to see and interpret them. This has been the case in the past, and it will assuredly be so in the future if we patiently carry on our physiognomical studies at the bedside. I find that Browning has put this idea in the following pregnant lines:

I tell you, men won't notice; when they do
They'll understand.

Lastly, allow me to hope that you will not regard these expressions of opinion as mere *obiter dicta*, suggestive of servile conservatism on my part, for I have come to these conclusions after a long experience and much thought. The views I have ventured to lay before you, imperfectly, as I well know, are not new. I think they are at the present time insufficiently recognized and applied in daily practice by many of us. At the end of the sixteenth century we find that they had not escaped the reflection of one of the greatest philosophers of all time, for in his *Essays on the Regimen of Health* (1597) we may note the following passage by Bacon (Lord Verulam): "Some Physicians are so regular in proceeding according to art for the disease, as they respect not sufficiently the condition of the patient." This is the moral of my words to-night, and I will leave it to your careful consideration.

REFERENCE.

¹ Dr. Omerod, *Harveian Oration*, 1908.

DR. F. W. TWTOR, in a paper on the influence of glucosides on the growth of acid-fast bacilli, presented to the Royal Society on March 4th, described a new method of isolating human tubercle bacilli directly from tuberculous material contaminated with other micro-organisms. Among 43 glucosides tested with acid-fast bacilli it was found that one—*crisol*—killed off a large number of species of micro-organisms, especially bacilli of the colon group and various cocci, but had very little effect on the acid-fast group of bacilli. By means of this glucoside, the isolation of tubercle bacilli directly from human sputum contaminated with other organisms became quite easy. A lump of sputum was placed in a 2 per cent. solution of the glucoside in distilled water, and kept at 38°C. for three-quarters of an hour to an hour. Pure growths of tubercle bacilli could then be obtained on Dorset's egg medium in fourteen to twenty-eight days. The tubes were sometimes contaminated with a few other organisms, chiefly tiny colonies of streptococci and slow-growing organisms of the streptothrix group, but they were so few that they in no way interfered with the tubercle colonies, which could be easily sub-cultured.

An Address

ON THE

DIAGNOSIS OF FEVER IN PATIENTS
FROM THE TROPICS.DELIVERED AT A MEETING OF THE WESTMINSTER DIVISION
OF THE METROPOLITAN COUNTIES BRANCH.BY
SIR PATRICK MANSON, K.C.M.G., M.D.,
LL.D., F.R.S.

I HAVE twenty minutes in which to speak about certain points which have to be attended to in attempting the diagnosis of fevers in patients coming from the tropics. The time is very short. I shall not waste it, therefore, in preliminaries, but proceed at once to my subject.

SOURCES OF FALLACY.

The first point I shall urge is a very important one. It is the necessity for the diagnostician to disabuse his mind of the very natural idea that because a fever has been contracted in or is occurring in a patient from the tropics it must necessarily be a tropical fever, symptomatic of some infection or condition peculiar to the tropics. This in my experience is one of the commonest and most misleading diagnostic fallacies. It so happens that my line of practice lies in great measure among patients from the tropics; but I am bound to say that half the patients from the tropics sent to me for an opinion or who come to me under the idea that they are suffering from tropical disease are not so suffering, although very likely they have fallen sick in the tropics or soon after return from the tropics. When you have dealings with a Scotsman you are apt to be obsessed with the preconceived idea of the national reputation for caniness, forgetting that, in the main, Scotsmen are very like other men, having the same physical, moral, and mental attributes. Just so, and perhaps even more so, in our contemplation of disease from the tropics. The major portion of a Scotsman's attributes is that of other men; only a very minor portion is peculiar. The major portion of disease in and from the tropics is ordinary disease; the minor portion special. Therefore when you encounter a fever in a patient from the tropics, think last and least (unless the diagnosis be glaringly obvious) of a tropical fever. Think first of and carefully test for those great and pandemic conditions—tuberculosis, syphilis, typhoid, malignant disease, and sepsis. If the seat and nature of the disease are not at once obvious, make it an inflexible rule to go over all the organs systematically, one after the other, beginning at the vertex and ending at the soles of the feet. I could tell many a story illustrative of the wisdom and necessity for this precaution—so obvious when stated thus pointedly, but, like so many other obvious things, so frequently overlooked or ignored. This is the first and perhaps the most important point I would make.

The next and equally obvious point I would impress on you is not to be misled by the diagnosis of malaria which in many instances the patient is nearly sure to volunteer. Patients' statements in this respect are apt to be very positive and correspondingly impressive. Such tropical cases come to you not so much with the idea of getting you to treat them on their own diagnosis. I have seen many cases of tuberculosis, of endocarditis, of liver abscess, of pyelitis, of syphilis overlooked for this reason. It should be an axiom with us never, without a thorough and independent examination, to accept another man's diagnosis, least of all a patient's diagnosis.

Having excluded as far as you can these sources of fallacy, then, and only then, you may conclude that the fever, let us suppose, you are trying to diagnose is probably a tropical one. Your next step should be to put to yourself the question, What are the tropical diseases likely to be brought to this country and which are associated with fever? Of course, we may safely exclude such acute and short fevers as yellow fever, dengue, and so forth; these need not be considered.

Tropical Fevers.

Let me enumerate what I might designate the important tropical fevers in the approximate order of the frequency with which they present themselves in practice here. First of all, of course, comes malaria; next, perhaps, hepatitis and liver abscess; then Mediterranean or Malta fever; next, and at a long interval, kala-azar, trypanosomiasis and sleeping sickness, relapsing fever, elephantoid fever, and probably other infections about which we as yet know nothing, but only suspect their existence. Each of the fevers I have mentioned has some feature or features by which it may be recognized, or, at all events, suspected.

Tests of Malaria.

Manifestly our first duty is to recognize or to exclude the commonest of them all—namely, malaria. Fortunately, this is easily done. Provided we set about it in the proper way and have a little time allowed us there is no disease so easily and so surely recognizable as malaria, for of this infection we have not one or two, but three absolutely pathognomonic tests. I am in the habit of describing these tests as, *first*, the clinical test of periodicity; *secondly*, the therapeutical test of the action of quinine; and *thirdly*, the microscopical test, the determination of the presence or absence of the malaria parasite or of its product, malarial pigment, in the blood.

There are other indications of malarial infection, such as leucopenia with relative increase of the large mononuclear leucocytes, enlargement of the spleen, and anaemia. These are only of relative value. Their absence is strong evidence against malaria, but their presence, seeing that they occur in other tropical diseases, does not prove the presence of malaria. They are not absolutely diagnostic in the same sense as are the three tests I have just mentioned, and need not be further considered.

The most important clinical test of malaria is *periodicity*—the periodic recurrence of the febrile or other phenomena. Practically all fevers, whether malarial or not, exhibit a periodicity. In tuberculosis, in typhoid, in sepsis, and so forth, there is a regular evening rise and morning fall of temperature, often quite as marked as in malaria. There is very definite quotidian periodicity. Quotidian periodicity is therefore not peculiar to, is no diagnostic mark of, malaria. We do meet with quotidian malarial fevers, especially in malarial countries. But quotidian periodicity, if taken alone, does not justify a diagnosis of malaria. So far from doing so, it is actually misleading. It is perhaps the most frequent cause of erroneous diagnosis in tropical patients. This you can readily understand. A patient from India, for example, comes to you with a story that every afternoon he has a shivering fit followed by a rise of temperature to 103°, and this again after some hours by a drenching sweat. He may mention no other symptoms. You may be in a hurry. You plump for malaria, and you prescribe quinine. The patient does not improve. You make a careful physical examination, and you discover signs of tuberculosis, or of liver abscess, or of some other form of visceral disease.

Quotidian periodicity, therefore, should be absolutely ignored in most cases as an indication of malaria. The periodicity characteristic of malaria, and absolutely diagnostic of that infection, is either a *tertian* or a *quartan* periodicity. These you find in no other condition, and are sure indication of malaria. The only circumstance in which quotidian periodicity may be a help in diagnosis is when the recurring fever sets in very late in the night, say after midnight, or before 12 or 1 o'clock during the day. Such a time for the commencement of a daily fever is almost peculiar to malaria.

The quinine test for malaria has usually been applied more or less intelligently before the case comes under the observation of the consultant. It is reliable if properly applied. Rarely does a malarial fever, in this country at all events, resist adequate dosing with quinine. Ten grains two or three times a day is almost sure in forty-eight to seventy-two hours to tell us whether we are dealing with malaria or not. But in employing this test we must be sure that the quinine is given properly, and that it is absorbed. Very often the quinine is given in adequate dose, but in some insoluble form, as in coated pill, flinty tablet, or insoluble sulphate. In catarrhal conditions of the stomach given in any of these forms the

drug may not be dissolved, much less absorbed, and cannot therefore be regarded as efficiently testing for malaria. When it is of importance that we should be certain of its action, quinine should be given in solution, or, in highly catarrhal or irritable conditions of the stomach, intramuscularly in doses of 7 to 10 grains. If no impression is made on a fever by quinine given in this way, do not blame the drug; revise the diagnosis.

Even more reliable than the clinical or the therapeutical tests of malaria is the microscopical test. If the malaria parasite or its product—haemozoin, or melanin, as it is usually called—is found in the blood, diagnosis is sure. The parasite of malaria is necessarily present at one time or another in the course of all malarial infections; it is always present in the visceral blood, nearly always in the peripheral blood, and, given certain conditions, can be readily demonstrated in the latter. It is necessary, however, to secure these conditions. In the first place the patient must not be under the influence of quinine, in the second place the person who searches for the parasite must know his business. Even a small dose of quinine—one, perhaps, quite insufficient to check the fever—may cause the parasite to disappear temporarily from the peripheral circulation. The possession of a microscope, and even skill in other departments of microscopy, do not always imply ability to recognise the malaria parasite. To do so satisfactorily requires experience—special experience—and long training. It is not a difficult matter, but, as with everything else, you must know how to set about it, and be familiar with the fallacies. It would be a conical list were I to enumerate all the various objects that have been brought to me as specimens of the malaria parasite.

I would warn you, therefore, to be careful about accepting a diagnosis of malaria from an inexperienced microscopist, but I would encourage you to have absolute confidence in the positive diagnosis, and in ninety-nine cases out of a hundred in the negative diagnosis of malaria from an experienced and conscientious microscopist.

Liver Abscess.

Assuming that we have to deal with a tropical fever and that by one or all of the tests I have enumerated we have excluded malaria, the question comes to be, which of the several tropical fevers I have mentioned are we dealing with?

Is the case one of liver abscess? The first and all-important question we put is—has the patient had dysentery or diarrhoea? If so there is, to say the least, strong presumption in favour of such diagnosis. We search, therefore, for local signs, for enlargement of the hepatic area, especially upwards, for local pain, oedema, or even redness. We inquire as to anaemia, progressive emaciation, for irritability and depression of mind; we look for a muddy complexion; we inspect the stools, looking for slimy or other indications of a former or an existing dysentery; we inquire for a dorsal or right dorsal decubitis, for shoulder pain, and we make a count for the white corpuscles in the blood—a leucopenia being against, a leucocytosis being in favour of, liver abscess. Finally, if the symptoms are reasonably suggestive we explore the liver under chloroform, being prepared to operate at once if abscess is discovered.

Mediterranean Fever.

We may suspect Mediterranean fever, more especially if the patient has come from Malta, although this disease is by no means unknown elsewhere—as in India, China, and even in Central Africa. The points in favour of a Mediterranean fever diagnosis are an undulant type of the fever, profuse sweats, the occurrence of marked rheumatic pains or of orchitis, and the absence of indications of other disease.

Apart from the symptoms mentioned the evidence for this fever is principally of a negative nature. The fever may assume all sorts of characters. Often it is undulant in type, but as often it is distinctly intermittent and quotidian, often of a low continued type, often a medley of all of these. The serum test is reliable under ideal conditions, but my experience of it in London is the reverse of favourable. When I employ it I usually send the blood to two different laboratories; as often as not I get "positive" from one and "negative" from the other. So I do not trust it here, although, where fresh cultures are

obtainable, it is quite as trustworthy as the corresponding test for typhoid, and even more delicate.

Kala-azar.

We have a patient from India, from China, from the Soudan, or from North Africa. He has a chronic fever, his spleen reaches to near his umbilicus, and his liver is very much enlarged. He has been ill for months; he is anaemic; his tongue is clean and his appetite and digestion are good; he has taken quinine by the pound, and he is gradually going downhill. Probably that patient is suffering from kala-azar—the disease produced by the Leishman body. To make sure of the diagnosis we study the fever chart—a four-hourly one; very likely we note that there are two distinct rises of temperature in the twenty-four hours. We examine the blood; there is a very marked leucopenia, more marked even than in malaria, and there is a relative increase in the large mononuclears. Possibly, though this is not likely, we may find a Leishman body or two, if we search long enough, in the white blood corpuscles. In the presence of such a fever and such a history we are entitled to puncture the spleen or liver and to search for the Leishman body in the juice or fragments of pulp so obtained. Such a procedure is not free from risk and must be done carefully, aseptically, and with a dry needle and syringe. I say "dry needle and syringe," for if a trace of moisture be present in these it will, by endosmosis, so distort the parasites that, though present, they may be hard to recognize. Of course, one must be familiar with the technique for their demonstration and also with the details of the structure of the parasite, for it is exceedingly minute and might be mistaken for a micrococcus or a blood platelet.

Trypanosomiasis.

The patient comes from tropical Africa. He complains of irregular fever, of great physical and mental lassitude, headache perhaps, tenderness of the limbs when he knocks them against any hard body. You suspect trypanosomiasis. You strip him and inspect his skin. You see great patches of erythema, many inches in diameter, usually having a ringed appearance and looking slightly puffy; you palpate the glands in his neck, axilla, or groin, and you find that some or all of them are enlarged—perhaps only slightly enlarged. The pulse, as a rule, is abnormally quick, and easily excited. That patient is almost surely the subject of trypanosomiasis, and may die of sleeping sickness. Examine his blood with a sixth objective, examining it especially during one of the recurring attacks of fever, and you are almost sure to find the trypanosome. It will not be found in every field of the microscope, and you may have to return to the hunt several times, but in the end you are almost sure to find it. If you fail to find it in the blood, puncture with a hypodermic needle one of the enlarged cervical glands, and examine the lymph so obtained; in it you have even a better chance of finding the parasite. The blood count is very similar to that of kala-azar.

Relapsing Fever.

The patient comes from India, from tropical Africa, from North Africa, or even from Gibraltar. He tells you that he has attacks of fever, perhaps violent fever, regularly about once a fortnight; that the individual attacks last from three to five or six days, that they subside nearly as suddenly as they begin, and that he is quite free in the interval. He may have had three or four or even eight or nine such attacks. What are they? The blood is negative for malaria; there is no marked leucopenia. Examine the blood during one of the fever paroxysms, and probably you will find the spirochaete of relapsing fever. In the African variety it takes some looking for. If you find it diagnosis is established. Such cases I have seen more than once in recent years in London. They were imported from Africa, from Gibraltar, and from India.

Elephantoid Fever.

Another patient may tell you he has attacks of violent fever coming on at irregular intervals of weeks, months, or years, that the attacks last for two or three days, and may be attended with severe rigor, delirium, high temperature, and be followed by profuse sweating. If he comes from the West Indies, particularly from Barbados, he will call this disease "fever and ague," but it is not

fever and ague as we understand it. It is not malaria; but elephantoid fever for the most part, and if we inquire as to the occurrence of inflammation and cellulitis of limb, scrotum, or acute lymphangitis, we are sure to find that such is the case. The patient is suffering from elephantoid fever, and is or has been the subject of filarial invasion.

The possibility of these various and very different infections should always be present to the diagnostician when he is called on to treat a tropical fever in this country.

Multiple Infections.

I began with a word of warning; I shall conclude with another word of warning, and it is this: Do not infer because you have found in your patient's blood or elsewhere the malaria or some other parasite, that you have the complete and full explanation of the case. In tropical disease malaria is apt to complicate everything, so that multiple infection of patients is rather the rule than the exception.

When you find the malaria parasite the patient has certainly got malaria, but that does not exclude other infections. I have sometimes been "caught" in consequence of ignoring this obvious precaution. Some years ago I was asked to see a patient just returned from Portuguese West Africa. He was said to be suffering from fever and dysentery. He had dysentery sure enough, and his spleen was enormously enlarged. He had taken much quinine; as it seemed to irritate his bowels I stopped it. At my first visit he had no fever. I found nothing in his blood. I left instructions that I was to be sent for should he have an attack of fever.

Some days afterwards I was sent for, his temperature being over 103°. I took a slide of his blood, expecting to find in it the parasite of malaria. Judge, however, of my horror when, instead of the malaria parasite, there was an unquestionable trypanosome staring me in the face! After a few days the fever disappeared, and, with the fever, the trypanosome also.

A fortnight later there was again a return of fever, and I again examined the blood, expecting to find the trypanosome. I found no trypanosome, but I found plenty of tertian malaria parasites. And so the case went on, every now and again a fever spell with trypanosomes in the blood, and every now and again a fever spell with malaria parasites in the blood. By the persistent use of atoxyl and of quinine both infections were finally expelled from the circulation. The patient is now, I believe, quite well.

Last year I had in hospital a patient from an African colony who carried about with him the malaria parasite, the trypanosome, the *Spirochaeta pallida*, the filaria, besides an assortment of intestinal parasites, including *Ascaris lumbricoides*, *Trichinurus trichinurus*, and *Ankylostoma duodenale*—a veritable museum, which, as long as it remained with us, we appreciated very highly at the Tropical School. He could always supply us with a subject for demonstration or for a clinical lecture.

I fear my exposition of the subject has been very sketchy and inadequate; it is necessarily so in consequence of the time limit imposed on me. I trust, however, I have given you the leading points for reliable diagnosis.

COMMON MISTAKES IN OPHTHALMIC PRACTICE.*

By ARTHUR C. ROPER, F.R.C.S.ED., M.R.C.S.ENG.,

SENIOR SURGEON TO THE WEST OF ENGLAND EYE INFIRMARY, EXETER;
SURGEON TO THE ROYAL DEVON AND EXETER HOSPITAL.

In casting round for a subject on which to write a paper which would prove interesting and useful, the idea came to me that I should formulate my impressions, gathered from twenty-five years of eye work, of the mistakes most frequently made by the medical men who have seen, and usually treated, eye cases before they came under my notice.

I use the word "impressions" because I have no statistics to give you. I do not commit to paper any mistake that I may think another man has made; but

yet, when one sees, as one does see, a considerable number of cases wrongly diagnosed and indifferently treated, they in a way sort themselves and occupy separate pigeon-holes in the recesses of one's brain. I should be sorry if this paper led any one to think that I pass a harsh judgement on a man who makes a wrong diagnosis on an ophthalmic case. I have lived too long and made too many mistakes myself to do this, and, moreover, I know very well the limited amount of experience in eye work that in the ordinary run of work falls to the lot of the general practitioner; and so, if any one finds in this paper a cap that he knows fits him well, let him not think that it is specially designed for his head, but rather consider that his head is fashioned on somewhat cosmopolitan lines, and is therefore capable of being fitted at the first ready-made and reach-me-down hat shop that he chances to enter.

Refraction.

The class of cases that provide the most numerous mistakes are undoubtedly refraction cases. One would expect this because refraction work forms such a large proportion of eye work, but I should think that, taking mistakes in this branch alone, they are quite in the proportion of 9 to 1—that is, that in 10 mistakes in eye practice 9 are due to bad refraction work. Nor is it astonishing that so many mistakes are made in this department, for while it has always seemed to me that constant practice at it is essential to its satisfactory performance, the public, and not a few of our profession, seem to consider that any one who sells spectacles is qualified to advise upon refraction troubles. When I occupied—as I did for twenty years—the post of assistant surgeon at the eye infirmary, where the bulk of the work is refraction, I always found that when I returned from my summer holiday my work took me half as long again as it was doing when I went away. Moreover, accuracy comes with speed, and you decide without hesitation such points as whether you shall give full correction in a hypermetrope, or whether it is worth while to give this child cylinders, or wise to give that myope a second pair of spectacles for near vision. These, however, are minor points, though they have oftentimes an important influence upon the reputation of the man whose work is bettered. The gross mistake, and the one which one most often sees, is where ciliary spasm in a hypermetrope is treated with -2 D. spectacles or -1 D.

The type of this is a young dressmaker, or perhaps a tailor's apprentice, who comes complaining that after a few hours' sewing things become misty and her eyes ache. She gets some relief by holding her work nearer to her eyes; but now this manoeuvre fails to relieve, and she is sure she needs spectacles. You test her, and find that she can read perhaps $\frac{2}{3}$ distant vision. You try her with a -1 D., and she says, "Oh, that's lovely; that's what I want"; or "Oh, yes, the print is beautifully clear." You provide her with the -1 D. or -2 D., whichever she sees best with, and she goes away seeing better than she has done for months, while you proceed to your next patient with the satisfactory feeling that "that is a good case." Next day your patient goes to work with a light heart, and finds everything very nice for a few hours; then the eyes again ache and smart. She thinks that they are not yet quite recovered from the bad treatment to which she subjected them before she obtained the glasses from you, and perseveres with them. But she finds that the aching returns at an earlier hour each day, and that her headache, which used to pass off when she left work, now persists all through the evening, and that only sleep, and even that not always, cures it. She then seeks other advice, is put under atropine, found to have hypermetropia, given her proper correction, and is thereafter comfortable, and wonders why you ever gave her those spectacles, which make everything look so tiny. The explanation of course is that you were deceived by the ciliary spasm. She came to you on account of this spasm. Her ciliary muscles, irritated by months of overwork in focussing correctly in a shortened eye had got to a condition of "tonic spasm" and over-accommodation, producing temporary short sight. You had easily corrected this short sight, but by doing this had added to her hypermetropia by precisely the strength of the concave glasses you prescribed. This led to greater efforts of accommodation, and to results which neither the eyes nor the patient could possibly put up with.

* Read before the Devon and Exeter Medico-Chirurgical Society.

Always, then, be exceedingly chary of ordering low concave glasses for anyone under 25 years of age, unless you have been able to ascertain definitely by the use of atropine that it is not a case of hypermetropia with ciliary spasm.

Squint.

Closely allied to this condition is that of internal squint in children. We so often get cases of bad squint brought to us with the history that it came on many months or even years ago; and, when we inquire why the parents did not see about it sooner, the reply usually is that "the doctor said the child would grow out of it." Now I am very far off believing all that people tell me about their doctors and the opinions that they have given. I know full well, from personal experience of the way people have interpreted and distorted my own opinion, how extraordinarily inaccurate the ordinary man, and still more so the ordinary woman, is in these matters; but this is such an oft-told tale that I feel sure the opinion is frequently given.* There is also some truth in the statement that the patient will grow out of it. "May" grow out of it would be quite true as far as it goes, but the whole truth would be "May grow out of it but with grievous loss of sight in the squinting eye and probable loss of binocular or stereoscopic vision." An opinion which causes any delay in the treatment of a squint in a child is hopelessly wrong and should never be given. For all practical purposes squint in growing children is always the result of refraction error. The exceptions are, in my experience, so few as to be negligible for the purpose of this paper, and the exceptions are usually caused by some lesion which is obvious and difficult to miss, such as corneal opacity. The vast majority of these cases of squint are convergent and when they are convergent they are associated with hypermetropia. When divergent they are usually due to myopia, or not infrequently to something which is rendering the diverging eye useless and so depriving it of the normal stimulus to move concomitantly with the other eye.

Let me briefly remind you of the physiology of accommodation and the supposed cause of converging squint; but first let me say that the last annual report of the Eye Infirmary shows that we had 97 cases of converging squint during the year and 10 of diverging; and of those 10 it is probable that not more than half were due to myopia.

As a working theory of the etiology or physiology of concomitant converging squint, Donders's is as good as any, and I can give you the outline of it in a few lines.

1. There is hypermetropia, that is, a short eye.
2. The short eye requires more accommodating power to focus objects on the retina than the normal or long (myopic) eye.
3. Convergence of the eyes is always associated with focussing. You will remember that the normal eye at rest is accurately focussed for distant vision. When objects nearer the eyes are looked at the internal recti converge the eyes so that they look at the desired point. Focussing—that is, increasing the convexity of the lens—also becomes necessary for a clear image to be projected upon the retina. Thus, convergence and accommodation are always associated, and so it comes about that convergence stimulates accommodation and increases it.

4. A hypermetrope of 2 dioptres has to be always accommodating to that amount to see distant objects clearly, and usually the ciliary muscle, which does the accommodating, manages it all right; but if the child gets some debilitating disease, or if anything occurs to weaken its ciliary muscles, convergence is brought into play to stimulate accommodation. Suppose, for example, that this hypermetrope wants a clear image of an object 30 ft. away. He converges to a point, say, 20 ft. away, and so excites the required amount of focussing. But if both eyes converge to 20 ft. neither will be directed towards the object at 30 ft.; and so it comes about that one eye is steadied by its own external rectus so that it looks at the desired object, while the other eye does convergence for both and so comes to be looking at only 10 ft. There you have the squint. One eye, the better one, is fixing the object to be seen, and the other is pro-

viding the necessary stimulus for accommodation by excessive convergence. We now come to the serious part of the business. It is obvious that the child will, the first time he performs this manoeuvre, see double, and so it soon comes about that the image of the converging or squinting eye is obliterated, and thus you get in most cases—

5. Amblyopia or impaired vision in the squinting eye. I will not even mention the many theories advanced to account for this. It is sufficient to say here that it does occur, and occurs so rapidly that some authorities think that the amblyopia is the predisposing cause of the squint, instead of the squint causing the amblyopia. Amblyopia means loss of sight, and it also means, if it is present to any important extent, loss of binocular or stereoscopic vision; and so I urge it upon you that at the first sign of squint you see that proper treatment by glasses is at once adopted.

All the treatment that is required at an early stage is correction of the hypermetropia by suitable glasses, and an operation for concomitant squint ought never to become necessary.

Ocular Headache.

One does not see nearly as many headaches from this cause overlooked as one did fifteen years ago. Medical men and the public have become thoroughly alive to the fact that this is a frequent cause of headache; but it is worth remembering that slight errors of refraction more frequently cause headache than serious errors. This is probably due to the fact that people with serious errors have them corrected early because they are aware that they cannot see properly.

Foreign Bodies.

Passing now from refraction troubles to actual pathological conditions, I will first just mention that minute foreign bodies in the cornea are a not infrequent cause of severe neuralgia in the forehead and temple, not are these foreign bodies always easily discovered.

A man came to me recently with a story of frightful attacks of neuralgia, for which he had been treated by his doctor for a month, with no good result. He considered that the neuralgia was in some way due to his right eye, because bright light was the chief exciter of the pain. The attacks were becoming more frequent and more severe, and quite incapacitated him for his work. He could not remember anything getting into his eye, and the eye looked quiet and normal, save that there was slightly excessive lachrymation and a very contracted pupil. I suspected some corneal trouble and had herpes in my mind when I examined the eye, but, after a careful and minute search with a lens, I found two minute foreign bodies. They were very difficult to find and see, but their removal cured his neuralgia, though not immediately. I saw him a fortnight later, and he told me that he had had a few attacks, all of them shorter and less severe than formerly, but none for four days past, and he considered that they were gone for good. As I have not had another visit from him, I feel sure that he is cured.

There are, somewhat rarely, cases in which a foreign body has got into the upper sulcus of the conjunctiva, where it is reflected from the orbit on to the eyeball; these are easily missed, and it is not sufficient merely to evert the tarsal cartilage and look for the body on its inner surface. With a bent probe or a spatula you should, after everting the lid, lift it off the eyeball and look carefully along the whole length of the upper sulcus. Eyelashes are specially prone to lodge here and cause irritation with mucopurulent secretion.

Corneal Ulcer.

I now come to a more serious group of cases in which eyes are often lost for want of careful and vigorous treatment at an early stage. Ulcer of the cornea, with hypopyon, following an injury which is often very slight. Almost invariably these cases arise among the poor, underfed, and hard-worked labourer, and in my experience from one of two causes. The man has either been stone-breaking and his eye hit by a chip of stone, or hedge-trimming, when it has been flipped by a twig or scratched by a thorn. The apparent injury may be so slight as to elude detection even with a corneal microscope, but the eye is usually painful, angry-looking, and watering. If you do detect anything by careful examination, it is a small scratch, abrasion, or cleanly incised wound, the latter from a sharp chip of stone.

Many men err from not treating this apparently slight injury with sufficient respect. They give a boracic lotion

*In the discussion following the paper Mr. Stirr, the Medical Inspector of School Children for Exeter, said that he could corroborate this statement, that parents of squinting children had often told him that doctors, consulted about the squint, had said "the child will grow out of it."

and perhaps some weak cocaine drops for the pain, and think that the eye will be all right in a day or so when the cut or abrasion has healed. A great many eyes are thus sacrificed every year. We had 20 such cases at the Eye Infirmary last year, and I doubt if one of them recovered with any useful vision, and I am sure that they provided a proportion of the eighteen eyes which were excised during that time. Such an eye should be treated as though it were inoculated with a virulent septic organism, as indeed it probably has been.

My advice to you is to send such a case to the Eye Infirmary at once. There is no money to be made out of them, because they have no money; there is no credit to be got from them, because if they get well they say that it was such a trifling injury that "of course it got well"; and if it does badly they say, and with some truth, "It was your fault." I always insist, when these cases come to me first-hand, that they shall come into the Infirmary. They require most careful nursing, antiseptic treatment, rest, and good food, and I cannot recall a case that has "gone wrong" when placed under these conditions. On the other hand, they go home with their bottle of boric lotion, which they pour into a dirty saucer, sop up with a not too clean cloth or rag, and squeeze into the eye with thoroughly septic fingers, and the eye does not get better. Slowly the cornea gets hazy with the hosts of leucocytes which muster to limit and destroy the invading and multiplying host of germs. The battle-field becomes a mortuary for the destroyed blood cells and germs, and this mortuary we recognize as a tiny yellow spot in the cornea—a minute abscess, which slowly, and day by day, grows larger. It not only loosens and destroys the surface epithelium, forming a shallow ulcer, but it penetrates inwards and perforates the inner, Descemet's, membrane, and the highly septic pus is then in the anterior chamber, to the bottom of which it gravitates as what we call hypopyon.

The local treatment which I adopt in the early stage of these cases is a drop of atropine, cocaine, and quinine. The atropine dilates the pupil before iritis sets in—a very good start. The cocaine soothes the pain, and the quinine is an efficient, sufficient, and un-irritating antiseptic. I also use a little yellow oxide of mercury ointment, and these, together with rest, good food, and thorough, frequent irrigation of the eye by a good nurse, are means which I find effective, sometimes even in cases which have reached the stage of abscess, and even slight hypopyon. If the case is a bad one, or threatens to be so, I cauterize the ulcer freely with the electric canter, let out the hypopyon by an incision in the corneal margin, and thoroughly irrigate the anterior chamber with 2 per cent. boric solution or with normal saline. I am getting to use the canter earlier and oftener in these cases, because I am convinced that the resulting opacity of the cornea is far less dense than is that which follows the natural cure.

Therefore, in cases of corneal trauma, especially from stone-breaking or hedging, watch with care and treat with vigour and precision. If possible, send them to an eye hospital for skilled nursing, rest, and feeding. If the case does well, a week or ten days in hospital will cure it; if it does badly, it will have been placed under the best conditions, and will be under treatment for many weeks.

Irido-Cyclitis.

Acute iritis is not often overlooked, but the low plastic type of irido-cyclitis is often most inefficiently treated, because its seriousness is not appreciated. I have had several such cases in the last two or three years, which have been mismanaged before they came to me, with vision reduced to less than $\frac{1}{100}$, with pupils not properly dilated, and so forth. Many are misled by the apparent mildness of the trouble. The eye is only very slightly inflamed, scarcely pink. There is absolutely no pain, and usually the only complaint is that sight is failing. On examination you may find that the iris does not react to light, or only very sluggishly. After atropine, you find that it has dilated either irregularly or not at all. Perhaps, if you are early enough, it dilates regularly but not fully, and you see spots of uvea on the lens. If you look at the fundus you find that the view is not clear, because there are cobwebby opacities in the vitreous; and, finally, close examination of the cornea shows you a few or many minute pin-point specks on its lower segment—keratitis punctata.

Such an eye is the seat of a very nasty and intractable disease. It will take months, running very likely into years, to recover, and will almost certainly suffer visual loss as the result of the inflammation which permeates it. The mistake which is usually made is that the iritis is recognized and treated, very likely correctly, with atropine, salicylates, iodide of potassium, or what not, and that the case is given up as cured when active iritic symptoms have passed. Men forget that the iris is, though physiologically a separate organ, anatomically continuous with the ciliary body and choroid, so that inflammation can, and does, spread backwards by continuity of tissue. In a case of simple iritis I am always very diffident about leaving off atropine, and watch the case anxiously for a month or two after omitting it from the treatment.

Do not forget that the iris is only the anterior termination of the uveal tract, and that an inflammation of it may spread back and involve the choroid, retina, and vitreous. Look out for keratitis punctata.

It may impress it upon your minds if I tell you that this condition is practically the same as that which you all know and dread as sympathetic ophthalmia. One sees very few cases of that nowadays, and there is no one here who would not at once recognize it if it arose in his practice after injury to the other eye. That is sympathetic irido-cyclitis, and what I have been speaking of is simple or, if you like, idiopathic irido-cyclitis, and is often as formidable a disease.

Glaucoma.

I feel that you will expect me to say something about the diagnosis between iritis and glaucoma, and at the same time I am conscious of being quite unable to condense the subject into a paragraph. The mistake is still made of using atropine for a glaucomatous eye, and is made in cases in which ignorance is not only the excuse for it, but the reason. A typical case of glaucoma in the acute or subacute stage is like nothing else. The suddenness and severity of the onset, the hardness of the globe, the partial dilatation of the pupil and its immobility, the shallow anterior chamber, and the steamy cornea, together with the rapid loss of sight, form a very perfect clinical picture. In iritis the onset is more gradual, the tension is but little if at all increased, the pupil is contracted and immobile, the anterior chamber is not diminished in depth, the cornea is not hazy, and the loss of vision is neither rapid nor, at first, great. But these are the easy cases to decide upon. One occasionally sees cases which give rise to great difficulty in diagnosis, and I believe that when you are in such a difficulty the best thing you can do is to order cocaine drops for the relief of pain, and send the case to a specialist at once.

I remember once having to do iridectomy for an acute glaucoma produced by the application of a mydriatic, by one of the best eye surgeons in England, for the purpose of investigating the condition of the lens. He suspected and found cataract, but he did not suspect chronic glaucoma, which was undoubtedly present, and which was exacerbated by the temporary dilatation of the pupil. Men occasionally, and at some risk, use a mydriatic in middle-aged and older people for the purpose of examining the interior of the eye for some unexplained loss of sight. Before doing this they should satisfy themselves that chronic glaucoma is not the cause for which they are seeking, because, if it is, they are running a very great risk of producing an acute attack.

Before using a mydriatic in a person of middle age or over, satisfy yourself that there is neither subacute nor chronic glaucoma present.

Chronic glaucoma is an insidious disease and a dangerous trap for which you should be always on the alert. I have recently seen two very sad cases of this disease in which total blindness was present when they came to me. The cases had passed, by months or years, the period when good could be hoped for from treatment. When a patient past middle age comes to me complaining of failing sight and with a normal looking eye, if correction of the refraction does not produce normal vision I think first of cataract and next of chronic glaucoma. The thing to bear in mind is that the disease is usually far advanced when the vision has become seriously affected, and that there is no time to be wasted in improving the general health in the hope that the sight will improve. The diagnosis in the early stages when treatment may avail to save sight is not easy,

and when the diagnosis is plain and the case a typical one' such as textbooks describe, treatment is too often of no avail. It is not very uncommon to find a case of this disease in an advanced stage but able to read $\frac{5}{6}$ and I.J., but when one examines the field of vision one finds it contracted to very small limits. This is, of course, because the intraocular pressure operates first on the periphery of the retina, where the vascular supply is more easily compressed than it is in the central portion.

It is difficult to give any "tip" for the diagnosis of chronic glaucoma. It always attacks both eyes, I think, but not together, so that if one eye has been lost from it you may expect it in the other. If you can make out that the tension is increased, you are safe in diagnosing it; but you are not safe in saying that a case is not chronic glaucoma because there is no increase of tension, because the tension varies a great deal in some cases, though it is probably increased at times in all. Nothing less than a careful routine examination of the eye and its functional power will suffice for making a diagnosis in an early stage.

Cataract.

There is one silly little mistake which I have made dozens of times, but have not communicated to the patient, in diagnosing cataract by focal (or side) illumination only. In some elderly people the hardened lens reflects the light in such a way as to give the pupil a milky appearance, which is not unlike the pearly reflection of a mature cataract. There is not necessarily cataract present in such a case, and the diagnosis is not good unless you can confirm it with the ophthalmoscope. With a plane mirror at the usual distance for indirect examination throw a light through the pupil on to the fundus. If cataract is present in the pupil you will see the red reflex interrupted by black streaks or dots or spots; or, better still, scrutinize the lens by the direct and close method, and with a +25 D. lens in your ophthalmoscope. That will show you the most minute traces of lens opacity, but requires some experience. The former method is quite sufficient for all practical purposes, and extremely simple.

CONCLUSION.

I have not exhausted the category of mistakes, and I have not mentioned the question of fundus conditions which cannot well be discussed until they have been demonstrated.

It was not my purpose to deal with the rarer conditions of disease or traumatism, or to exhaust the possibilities of the eye as a field for making mistakes in. I have contented myself, and I expect tired you, with the common mistakes in ophthalmic practice.

THE VALUE OF SOME LACTIC ACID FERMENT PREPARATIONS FOR INTESTINAL THERAPY.

BY

I. WALKER HALL,
M.D.,

and

W. A. SMITH,
M.B.Oxon.,

PROFESSOR OF PATHOLOGY AND
BACTERIOLOGY, UNIVERSITY
COLLEGE, BRISTOL; AND
PATHOLOGIST, BRISTOL
ROYAL INFIRMARY.

BRISTOL; LATE SURGEON,
SAFFRON WALDEN
HOSPITAL.

DURING the course of an investigation upon faecal organisms it was found necessary to determine the inhibitory action of certain types of lactic acid bacilli. Some of the bacilli were isolated from ten commercial lactic acid ferments, and it was suggested to us that a statement of our observations might be of interest to those who use these ferments in everyday practice.

The majority of these ferments are sold in the form of dry tablets, obtained by inoculating the milk with an organism, evaporating, and then compressing the residue, or by mixing a dried culture of the organism with a suitable excipient. These tablets are directed to be added to milk which has been boiled for a short time and then allowed to cool; the milk is then to be kept at blood heat for six to eight hours. After this period of incubation the milk is said to be sufficiently "soured" for therapeutic uses. In a few cases it is advised to dissolve the tablets

in sweetened water before consumption. The object of these procedures is the introduction of lactic acid bacilli into the ileum and colon in order to inhibit the action of putrefactive bacteria.

The results of the simple experiments we have carried out tend to show that the ferments at present on the market do not achieve the end in view, and they suggest that until there is a decided improvement in the processes of manufacture the dangers attendant upon the use of these tablets outweigh their benefits. Whenever the treatment is specifically indicated it would be well to obtain young, active, and specially adapted (aerobic and anaerobic) cultures in a fluid medium from local public health or other laboratories, and to determine the efficacy of the organism by bacteriological examinations of the faeces. With suitable media and precautions, such a proceeding need not involve more than the outlay of a few shillings, and the ultimate expense will be considerably less than that occasioned by the longer haphazard medication with inert or inefficacious material.

Development of Acidity.

Since the ferments are used in connexion with milk, we first determined the acidity developed in raw, pasteurized, and sterilized milk during incubation at blood heat. It will be seen from Table I that in pasteurized and sterilized milk a considerable amount of acid is formed, and that it is necessary to sterilize the milk on two successive days in order entirely to free the milk from micro-organisms.

TABLE I.—The Acidity Developed in 25 c.c. of Milk during Incubation in Sterile Flasks at 37° C. (98.5° F.).

	Acidity when received, Deci- normal Alkali.	24 hours. Deci- normal Alkali.	72 hours. Deci- normal Alkali.	96 hours. Deci- normal Alkali.
Raw milk	12	25.0	96.0	—
Pasteurized milk	6	11.5	19.5	21.0
Pasteurized milk, the acid produced each 24 hours being neutralized	6	11.4	30.9	63.4
Pasteurized milk heated to 100° C. for 1 hour	6	13.0	29.0	36.5
Pasteurized milk heated to 100° C. for 1 hour on two successive days	6	—	—	—

These figures emphasize the observations of Robertson and Muir,¹ who found that:

Milk pasteurized at 70° C. for 30 minutes killed off cocci, lactic acid coli, proteus, and ordinary pathogenic bacilli.

Milk heated to 100° C. for 1 to 1½ hours killed off anaerobic spore-bearing bacilli, including *Bacillus enteritidis*.

Milk heated to 100° C. for 2 hours killed off subtilis group and aerobic spore-bearing bacilli responsible for summer diarrhoea.

As it rarely happens that the domestic heating of milk ensures complete sterilization, it is obvious that the addition of "ferments" to milk partly sterilized induces considerable antagonism between the added bacilli and the unkilld organisms, which, freed from the restraint of the ordinary milk bacteria, are multiplying more rapidly than usual. In summer time some of these resistant organisms possess pathogenic properties, and their free growth is not without danger. If this form of treatment demands the "souring" of milk, it is obvious that the process should be carried out with new milk collected under cleanly conditions. The slight bactericidal properties of fresh milk may then act upon undesirable organisms and the lactic acid bacilli outgrow other bacteria. As this, however, requires several days for completion, we are forced to the conclusion that the conditions of the collection and sale of milk in this country make it an untrustworthy vehicle for the administration of this medicament. It is better, apparently, to discard milk and to administer the cultures in a liquid sugar medium.

I.—The Acid Contents of the Tablets.

It appeared to be worth while to determine the acidity of each tablet in order to ascertain the activity of the medium from which the tablet was prepared. The figures

obtained show considerable variation (vide Table II). The smaller amounts are from those tablets which consist of a mixture of dried bacilli and sugar only.

TABLE II.—*The Acidity Obtained by Dissolving the Tablets in 25 c.cm. Distilled Water in Terms of Decinormal Alkali.*

Sample No.	7*	c.cm.
..	No. 4	0.5
..	No. 6	0.4
..	No. 8	0.05
..	No. 8	0.2
..	No. 5	1.8
..	No. 1	0.5

* The numerals are adopted for convenience only. They have no relation to the order in which the preparations are cited.

Morphologically the appearances of the organisms differ widely. Some tablets contain bacilli which accord with Metchnikoff's classic descriptions: in other preparations diplococci, sporulating bacteria, and streptobacilli, or yeasts are also present.

Speaking generally, there is no growth on McConkey's medium, but luxuriant cultures are obtained in peptone broth, nutrient broth, dextrin, glucose, saccharose, lactose, salicin, glycerine, and raffinose, and on nutrient agar. Sorbite, galactose, maltose, inulin, dulcitol, and malachite green broth rarely act as suitable media. Nitrates are only reduced by one or two types and indol reactions are not obtained.

II.—Variations in the Power of the Tablets in Each Sample.

The power of the tablets may be ascertained by incubating measured quantities in a 1 per cent. lactose solution. Their activity should be determined by incubation in a lactose solution to which carbonate of lime is added in excess. The capacity of multiplication is another factor for estimation, and from our standpoint one which is of prime importance. These factors often show considerable variations, so that they must be severally investigated.

In Table III are recorded the "powers" of the tablets. It will be seen that there are pronounced differences between the samples examined, and between individual tablets from the same batch. This may to some extent account for the complaints of irregular "souring." In some instances the acidity developed after twenty-four hours is not greater than when the original tablet is dissolved in distilled water.

TABLE III.—*Variations in the Power of the Tablets of Each Sample. Estimations of the Acidity Produced in Milk by adding One Tablet to 25 c.cm. of Sterilized Milk or 1 per cent. Lactose Solution free from Carbonate of Lime (in Terms of Decinormal Alkali). Incubation Period, 48 Hours at 37° C.*

	Tablet 1	Tablet 2	Tablet 3	Tablet 4	Tablet 5	Tablet 6
Sample No. 5	2.0	0.5	0.6	0.4	0.4	0.2
.. No. 1	7.1	6.1	4.2	2.8	2.8	1.8
.. No. 8	0.3	0.3	0.2	0.2	0.2	0.2
.. No. 4	4.0	3.6	3.6	3.4	2.8	2.8
.. No. 6	0.4	0.3	0.3	0.2	0.2	0.2
.. No. 7	0.7	0.6	0.6	0.6	0.6	0.6
.. No. 2	3.5	3.2	2.6	2.6	2.4	2.1
.. No. 3	0.7	0.6	0.5	0.5	0.5	0.4

It may be well, however, to point out that the best acidifiers are by no means the best multipliers and that the amount of curd is not an index of the capacity of the organism to pass through the alimentary canal.

III.—The Activity of the Ferments in Pasteurized, Partly and Fully Sterilized Milk, and in Lactose Solution.

The figures given in Table IV represent the activity of the ferments. It will be seen that pasteurized milk

without the addition of a tablet yields approximately the same amount of acid as that produced after the addition of the ferment. From Table V it appears that the ferments possess more power than the proliferating organisms of pasteurized milk. During the first twenty-four hours only three of the samples show any marked acidity; the others are not more acid than the pasteurized milk. Some of the ferments inhibit the action of the normal acidifying organisms.

The manufacturers do not advise the use of pasteurized milk. According to the directions it is necessary to bring the milk to the boil—some go so far as to recommend the difficult task of keeping it on the boil for one hour—then to cool it, and after adding the tablets to keep it at blood heat for six to eight hours. In Table VI the results of an attempt to follow the instructions given are recorded, and they represent what would be obtained by a nurse or housewife. The figures show that the unskilled organisms are able to grow rapidly in the milk, and that the introduction of the lactic acid bacilli produces an antagonism leading to a minimal growth of both types of organism and a small amount of acidity. When inert, or almost inert, tablets are added to the milk, it is evident that the spore-bearing organisms of the milk have it all their own way, and as such bacteria sometimes act as intestinal irritants, the process cannot be considered as a safe one. Were it possible, however, for the "souring" to be obtained within six to eight hours this danger would be only trifling; but this time is far too short for the hibernating bacilli to regain their normal activity, and upwards of sixteen to twenty-four hours is the average period necessary. Table VII shows the conditions when the spores are all destroyed, and the tablets exhibit their maximal characters.

IV.—*The Inhibiting and Antagonizing Action of the other Organisms present in Milk.*

We have already remarked upon the inhibitory action of the milk organisms upon the lactic acid bacilli. The following table points the moral. When *B. coli* are present in milk they reduce the activity of any added lactic acid bacilli. In this instance comparative quantities of *B. coli* and *B. acidilactici* were added to a sterile lactose solution, and in many cases the acidity produced was less than that produced by the lactic ferments alone. We may fairly assume that with the ordinary "souring" of milk the conditions are more complex, and that it is too much to expect the dried bacilli to attain their dominating characters until the other organisms have developed a strong antagonism.

TABLE VIII.—*The Activity of the Lactic Acid Ferments in 1 per cent. Lactose Solution, and the Inhibiting and Antagonising Action of other Organisms.*

To 25 c.cm. of a 1 per cent. freshly prepared lactose solution $\frac{1}{2}$ c.cm. of a twenty-four hours' growth of the organism in nutrient peptone was added. The mixture was then incubated at 37° C. (58.5° F.).

V.—*The Multiplication of the Lactic Acid Bacilli.*

During the passage of the lactic acid ferments into sugar and other media a good growth was invariably obtained in peptone water. Fournier² points out that with certain true lactic ferments the lactic acid output may exceed 100 per cent. in the presence of peptone, and this without giving rise to any simplified nitrogenous product, or to any putrefactive one particularly. It is evident, therefore, that peptone water is essential for the multiplication of the bacilli. Critchard³ has recently observed that the lactic acid bacilli grow best in an acid medium, and Coheny⁴ devised a medium composed of lacmus milk containing 35 grams lactic acid per litre. Palier,⁴ however, working lately in Boas's laboratory, finds that gastric juice kills bacteria with ease, and considers that the lactic ferments are devitalized before they reach the intestine.

As the lactic acid treatment aims at intestinal therapy it seemed advisable to subject the tablets to the action of an artificial gastric juice. After some preliminary failures a medium was found which was comparable with gastric juice and yet contained stimulating pabulum. This medium later proved to be a very useful means of isolating the organisms from the dejecta, and a valuable form of enrichment. Table IX shows that a proportion of the tablets did not survive this test. The small amount of acid contained in these tablets (vide Table II) suggests that the organisms were not prepared from a very acid medium, and that, in order to safely navigate the gastric sea, the bacilli should be trained to appreciate an acid medium; in other words, the medicament should be a culture grown and administered in an acid broth.

VI.—*The Action of Aerobic and Anaerobic Faecal Bacteria upon the Lactic Acid Bacilli.*

Tables X and XI contain the results of the interaction of normal and pathogenic bacteria and the lactic ferments. It shows that very few of the preparations are sufficiently active to overcome the faecal bacteria, and that an acid medium is an important factor in the process.

TABLE X.—*Activity of the Lactic Ferments in Presence of Aerobic and Anaerobic Faecal Organisms.*

Measured quantities of the organisms and of an emulsion of faeces were mixed together and incubated at 37° C. for varying periods. Cultures were then made in acid and neutral broth, and the organisms plated on agar and McConkey's medium.

VII.—*The Passage of Lactic Acid Ferments through the Alimentary Canal.*

It is a generally accepted statement that the lactic acid bacilli appear in the faeces about five days after being taken by the mouth, and that the total amount of faecal

bacilli is at once diminished, the lactic acid bacilli being easily demonstrable in the dejecta for some time afterwards. We find, however, that with suitable doses of enriched cultures accustomed to live under anaerobic conditions, and administered in a specific acid medium, there is no difficulty in demonstrating the presence of the bacilli in the stool passed the following morning.

It is not an easy matter to recognize the various lactic acid bacilli in the faeces, and only when we adopted the acid "gastric" medium referred to did we find the procedure at all simplified. By this means, however, the recognition is neither difficult nor tardy, and the practitioner is assured of a practical demonstration of the object he aims at.

These lactic acid bacilli are not in their natural habitat when transferred to the colon, and it is curious that their life in the intestine is about the same as it is in artificial media—namely, about five to seven days. This seems to be the period when another dose is indicated. The fact suggests that we must not expect these bacilli to become acclimatized to the intestine easily, and must regard them rather as temporary interlopers, our object being to allow the normal flora to regain their sway as soon as the objectionable putrefactive anaerobes are overcome.

Passage of Lactic Acid Ferments through the Alimentary Canal.

Tablets from the various preparations were taken by the month. When the organism appeared in the faeces the ingestion was stopped, and the faeces examined daily until the lactic acid ferment could no longer be isolated.

TABLE XI.

Period of Ingestion.	First Appearance in Faeces.	Disappearance from Faeces.
Tablet (1), Feb. 1st to 10th ...	No appearance	—
Tablet (6), Jan. 30th to Feb. 3rd ...	No appearance	—
Tablet (3), Jan. 30th to Feb. 1st.	February 1st	February 4th
Culture, Feb. 1st to 2nd ...	February 2nd	February 8th
Culture (6), Feb. 3rd to 4th ...	February 4th	February 10th

It only remains to make the deduction that even the best present commercial preparations are not sufficiently and regularly active for routine use, and that freshly prepared fluid cultures should be employed when lactic acid therapy is indicated. The activity and power of the organisms in producing acids cannot be taken as an index of their multiplication and inhibitory action upon other organisms, and it is probable that no one organism can be regarded as efficacious in every case. When an organism fails to produce the desired result, certain laboratory tests may indicate the selection of bacilli possessing other characteristics. It should also be borne in mind that the lactic acid therapy is only indicated when the putrefactive anaerobic organisms are present in the faeces in excess, and that without such a guide this form of medication may aggravate rather than ameliorate the intestinal conditions.

MESSRS. HARVEY FROST, who are well known as the manufacturers of a very useful portable tyre vulcanizer, have issued a pamphlet, which they will present to persons interested, containing certain particulars of various motor tyres upon the market. No opinions are expressed upon their relative merits, but it contains some useful hints as to the management and repair of tyres. Specimens of all those mentioned can be seen at Messrs. Harvey Frost's, 27, Charing Cross Road, where they are not on sale, and therefore can be inspected and compared without any order being expected.

An Address ON MINING ACCIDENTS:

WITH
AN ACCOUNT OF THE USE OF OXYGEN IN A
COALPIT ACCIDENT.

DELIVERED TO THE STIRLING BRANCH OF THE BRITISH
MEDICAL ASSOCIATION

By JAMES ROBERTSON, M.B., C.M.

CLACKMANNAN; PRESIDENT.

GENTLEMEN,—I accept it as an honour to have been asked to address you, and I hope that what I have singled out of my scrapbook may be of interest.

COMPLETE DISLOCATION OF KNEE-JOINT.

In the following case there are three points to which I desire to call particular attention:

1. The free mobility of the limb at the knee-joint. One of the classical signs of a dislocation is no movement where there ought to be movement; in dislocation of knee-joint there is increased mobility, and mobility in every direction.
2. The floating patella, which simulated a patella in a case of acute synovitis with effusion; the difference being that upon comparison with the other limb the patella was 3 in. higher.
3. Was the entire absence of pain due to the amount of crushing and local stunning of tissue and nerves from the violence of the wrench?

J. M., a drawer, aged 20, was brought home from his work injured on February 19th. He stated that a hutch containing a load of coal—total weight 15 cwt.—was proceeding down an incline when it left the rail. He went in front to replace it, and when he had done so it ran away, catching his foot between the hutch and a sleeper, the toe of his boot being caught by the sleeper, his heel by the hutch; the hutch, moving on, carried his foot to extreme flexion, when the hutch broke and tilted upon his leg. He became helpless and was removed home.

Condition on Examination.

The limb was shortened and the region of the knee-joint enlarged; there were several bruises between the knee and ankle on the posterior aspect of the leg; the limb was freely movable in any direction at the knee-joint; neither crepitus nor any other sound elicited; there was no pain. Posteriorly the entire articular surface of the femur was felt, the rounded condyles and the notch between them. Anteriorly the patella was freely movable in any direction, and could be pressed down upon the anterior aspect of the femur. The rectus femoris was raised from the femur, and could be grasped easily with the fingers upon displacing the patella; the entire articular surface of the tibia could be felt; the cup-shaped depressions, with the spinous processes; the crucial ligaments could be felt torn; no pulsation could be felt in the tibial arteries at the ankle-joint.

Treatment.

I administered chloroform and set the joint by grasping the ankle with my right hand, placing the femur near the knee on my left thigh, and combining extension with flexion, the joint replaced itself with a loud snap. I again examined, and found the parts normal so far as the bones were concerned, the patella gliding normally over the condylar surfaces, and the replaced joint moving normally and without pain. The limb was wrapped in wadding and a posterior splint applied.

On the day after the accident the patient complained of severe pain round the ankle, and described it like a rope tied tightly there. He had been restless all night. The knee-joint was greatly swollen, and the patella floating, owing to great effusion into the joint; there was no pain, except upon pressure. The foot was bluish and cold, and superficial sensation was lost; deep sensation was present, but feeble; several patches of skin on the leg were ecchymosed, and there were three small blebs, containing dark serum, in the popliteal space. These I pricked and dressed; the foot was rolled up in flannel, and a hot iron, also rolled in flannel, kept at it; a saline purge was given.

On the third day the swelling in the joint was greatly reduced, the bowels had moved, and he had a good night, but complained of sharp shooting pains occasionally passing up the leg from the foot.

On the fourth day the knee was normal in size and looking well; the dressings were removed, and movement begun. Dry gangrene was starting in the toes; all sensation in the foot was lost, but there was hyperaesthesia round the ankle-joint. The gangrene gradually extended from the toes to the foot, until the patient was removed to the Victoria Hospital, Glasgow, for operation seven days after the accident—February 26th.

During the first four days' residence in hospital the patient became febrile and began to show the characteristic chart of septicæmia. The calf of the leg began rapidly to swell, and became boggy. This was incised on March 1st, when pus escaped, and at the same time the gastrocnemius and soleus muscles protruded out of the wound, showing that they had been torn at the time of the accident. The septic condition was the result of absorption of poisonous products from the gastrocnemius and soleus muscles were torn at the thickest fleshy part, and there was a great deal of tissue bruising. There were no blood clots in the veins, and no signs of any injury to vessels. The foot was black.

The limb was amputated at the lower third of the femur on March 4th. The patient made a slow but good recovery, and is now working at the pit head, using an artificial limb with freedom.

Examination of Amputated Limb.

The knee-joint was found to be as I have described; the gastrocnemius and soleus muscles were torn at the thickest fleshy part, and there was a great deal of tissue bruising. There were no blood clots in the veins, and no signs of any injury to vessels. The foot was black.

I have seen the record of five such cases in England, and one in Scotland, and in all the cases gangrene of the foot resulted and necessitated amputation of the limb.

FRacture of Cervical Vertebrae.

I have now seen several cases of spinal fracture; by that term I include cases of spinal dislocation, as it is impossible to distinguish between the two, when either is grave and involves pressure upon the spinal cord.

The spinal cord terminates at the lower edge of the twelfth dorsal vertebra, so that fracture of the lumbar vertebrae involves only the nerves, and when the pressure is removed paralysis usually disappears, but fracture of the dorsal or cervical, as a rule, not only causes pressure upon, but rupture of the cord, and in these cases death sooner or later results. In three cases I

have had of dorsal fracture death resulted during the third year. The higher the injury the more serious and the more rapid the case. In the following case the fracture was an exceptional and interesting one to study.

J. M., an inspector, aged 59, going his usual rounds, reached a coal face, where the miners were sitting at rest. He also sat down in the miners' usual position, that is by extreme flexion of knee-joints, almost sitting on his heels, with his back against the side of the workings. While sitting there a large stone, weighing about 1½ cwt., shot out from the roof above him; its edge struck him upon the forehead, causing sudden over-flexion of the chin upon the chest.

Condition on Examination.

There was no external injury beyond a slight graze on the forehead. There was great mobility of the head and of the cervical region, in any direction, giving a feeling of looseness; there was general paralysis and anaesthesia up to the level of the fourth rib; from the fourth rib to the clavicle there was slight sensation; the arms could be moved with great difficulty, and sensation in them was impaired; above the clavicle sensation was normal. The only movement to be seen was movement of the head with pain and movement of the diaphragm. The ribs were fixed owing to complete paralysis of the muscles of respiration, even of forced respiration, the breathing was Cheyne-Stokes type, the pulse was of low tension and feeble, and the heart sounds weak. The seat of injury was at the sixth and seventh cervical vertebrae.

The man lived sixty hours, the pulse and heart showing pro-

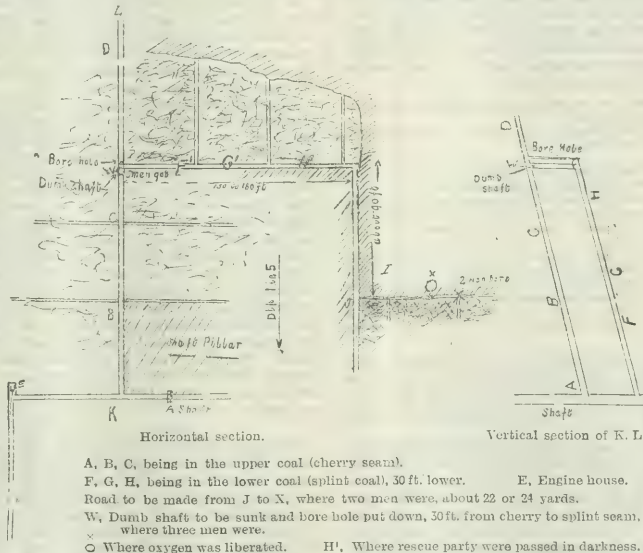

gressive weakening, until death resulted from extreme lividity and a great struggle for breath. The bladder and bowels had to be relieved.

The interesting points of this case are:

1. The brachial plexus arises from the fourth cervical to first dorsal; the fracture being between the sixth and seventh cervical involved the major part of this plexus, hence the partial paralysis of the arms and the diminished sensation, so that while movements of arms existed, they were a terrible burden (as the man expressed it), the nerve power of the fourth and fifth not being sufficient to carry the weight of the arms. This experience makes one think of the relation of the nervous system to the physical frame—the power of the nervous system, and the weight of the physical frame. If the nervous system of the individual is in proper working order, the physical frame has no conscious weight; if the balance is upset, then the physical system is a conscious burden.

2. Breathing was carried on by the diaphragm alone; one could watch the abdomen rising and falling as the man gulped the air, but the chest was absolutely still. Here the pneumogastric and phrenic nerves did their duty. The pneumogastrics, arising from the medulla and passing direct from the skull into the neck, escaped injury. The

phrenics, which arise from fourth and fifth cervical, pass down the middle mediastinum to the diaphragm. The laryngeal nerves, being branches from the pneumogastrics and supplying sensory and motor branches to the larynx and the muscles of the cord, the voice was natural. It is also worthy of note that the sterno-mastoid muscles were strained and out-standing, showing that the spinal accessory nerves were uninjured. They arise from the cord in the region of the fifth and sixth cervical, and passing up the

spinal canal appear in the neck through the foramen lacerum posticum, and supply motor fibres to pneumogastrics. The area of sensation was also limited to the distribution of the cervical plexus and the uninjured part of the brachial plexus. The cervical plexus is divided into three parts—ascending, descending, and deep. The area covered by the two former extends from the clavicle to the lower jaw; the sensation over this area was normal. The deep cervical includes the phrenics, which are the motor nerves of the diaphragm. The muscles of forced respiration have their nerve supply from the brachial plexus; they, therefore, were paralysed.

THE VALUE OF OXYGEN IN PIT RESCUES.

Pretoria Pit, situated about one mile from Clackmannan, is worked in two seams—an upper seam, 35 fathoms deep, and a lower seam, 40 fathoms; that is, there are 5 fathoms or 30 ft. of rock between the upper and lower seams; the gradient is 1 in 5. The pit is surrounded on all sides by old workings, containing water and foul air. Three-quarters of a mile to the west of the pit is a large unworked quarry, covering several acres of ground, and about 40 ft. deep, full of water; an old pit shaft opens into this quarry. The drainage of the surrounding district is led into this quarry. The water suddenly broke into the lower seam, and shortly

afterwards it was found that the water level of the quarry had fallen rapidly. After the flooding was complete the whole amount of air in the lower seam would be about 20,000 cub. ft., coming from all the various passages and openings of every description. All the men except five escaped. Three of these were in the rise of one road, two were locked up in another. The three had about 70 yards of road to creep about in. The two were locked up in a space 2 ft. 6 in. high, 3 ft. broad, and 18 in. from tail of water to coal face. They were sitting with their backs against the coal face and their feet in the water.

The sketch is a rough horizontal plan of the lower seam.

The men were discovered in the usual way. They scored the roof with a stone, and the sound was heard by the search party in the upper seam.

After ten hours' working with pumps it was found impossible to gain on the water, and it was decided to sink a dumb shaft from the upper to the lower seam, near the point where the men were heard knocking. Before starting the dumb shaft, a 3-in. bore-hole was rapidly put down, when it was discovered that there were only three men here, a father and two sons; another search was made, when the other two men were located, a father and son. The three men were fed and kept supplied with candles through the bore-hole until rescued. The pit chart showed the other two men to be in such a perilous position that nothing could be done from the upper seam to save them.

The study of the rescue resolves itself into two stages, in so far as the air island is concerned:

First Stage.—During the entombment of the five men prior to the shaft being sunk.

Second Stage.—During search and rescue of the two men after the shaft was sunk.

First Stage.—There would be about 20,000 cub. ft. of air kept in motion, as to be here described, and all available.

Second Stage.—The air space at once became limited to about 7,000 cub. ft. for all purposes, as now the air tended towards the dumb shaft, and left only the air of the passage we were actually in—500 × 3 × 4 ft.

Oxygen was liberated in a space 90 × 3 × 4 = 1,080 cub. ft., and gradually worked its way to the dumb shaft, oxygenating 7,000 cub. ft. of air, or an air area equal in size to that contained in an ordinary drawing-room, scattered throughout which were twenty men. It took three hours to complete the rescue, so that each man had roughly 2 cub. ft. of O₂ for three hours, which proved sufficient.

When the pit was suddenly flooded, on February 3rd, 1906, at about 9.30 a.m., the section where the men were entombed was completely isolated by water, and they were left in an island of air, which was compressed by the sudden roofing of the water.

This section was a main road with several side roads leading from it, the average height being about 2 ft. 9 in., the breadth about 5 ft., and the length about 70 yards. The contained air of this main road and the side roads was estimated at 20,000 cub. ft. The five men were breathing this air for four days, three of them also having a light burning, and thus causing an alteration of the component parts of the air, diminishing the oxygen and increasing the percentage of CO₂. The other two men were in darkness.

On February 6th at 8 p.m., when the sinking of the dumb shaft was completed, the compression was relieved, and exhalation at once began until air equilibrium was established. This exhalation of air diminished the amount of air in the lower seam. After the three men were removed twenty men now went down the shaft, and proceeded to effect communication with the remaining two men still entombed. In about three hours a stage was reached at which lights would not burn, and breathing was only possible with difficulty; work had to be suspended, and the rescuers were left in darkness. An interesting question here arises: (1) What is the lowest percentage of oxygen compatible with conscious life? (2) What percentage of CO₂ gas may be mixed with air and yet conscious life be supported, and for how long?

At this stage, which was midnight February 6th-7th, about 40 cub. ft. of oxygen was liberated at a point about 150 yards from the dumb shaft, and several feet from the two imprisoned men. This so altered the air condition that lights were got to burn, breathing became easy, and work, which had been suspended, again commenced. The oxygen supply was kept up as required until 4 a.m., when we all arrived at the upper seam.

EFFECT OF CHESTING WATER UPON AIR CONTAINED.

During February 4th, 5th, and 6th, while the dumb shaft was being sunk, and before the complete penetration of the rock strata, the air was confined and compressed between the tail of the water in the various roads on the one side and the coal face on the other. The tail of water was a movable, the coal face a fixed, quantity. The water chests, proceeding up and down the shafts, impinging against the water in the shaft before filling, and lifting each time about 1 ton of water to the surface, set up a movement along the water throughout the pit, thereby causing for each impingement a tidal move at the tail; this tidal movement communicated itself to the confined air at various points surrounding the places of entombment, and thereby kept the air in motion, causing a continuous mixing and aiding ordinary physical diffusion, thus preventing stagnation of CO₂ gas produced by the breathing and lights.

On the evening of February 6th, when the shaft was sunk, compression was relieved, exhalation took place, and although chesting was continued the movements now communicated from the water to the air became less effective, as all air movement at once tended towards the point of least resistance, the dumb shaft.

It follows: (1) That as the dumb shaft was a funnel from the lower seam to the upper, and the only opening, no air could be sent down that shaft. (2) That the twenty rescuers in the lower seam were consuming and burning the air oxygen, and liberating CO₂ gas at a point about 150 yards away from the dumb shaft.

The CO₂ gas rapidly increased, and any movement communicated from the water to the air simply mixed a highly poisoned air with a less poisoned air, as no fresh air could gain entrance; during this time also the water level was lowering, and there is no doubt that CO₂ gas, or black damp, was creeping on us from some old workings. At this stage, when lights went out owing to CO₂ gas, it mattered little whether water chests impinged on water or not, as all the confined air was highly charged with CO₂ gas, and all air movement was towards the dumb shaft.

The only thing now was to liberate oxygen as near as possible to the imprisoned men; a displacement of gases followed, and a diffusion of oxygen through the poisonous air; the oxygen effect beginning at the point of liberation, and gradually working its way backwards to the dumb shaft. This is what I expected, and what happened. During this final stage the rescuers were in an atmosphere of CO₂ gas in which no lights would burn for about fifteen minutes.

PROOF OF OXYGEN TRAVEL.

When proceeding down with the oxygen from the dumb shaft, the first few yards of our journey lights burned; as we went in they gradually lessened, and finally went out; about 80 yards in we passed some of the rescue party scattered and sitting in darkness; we proceeded about 60 yards in advance of them, and then gradually liberated the oxygen. The lights were soon set burning at the point of liberation, and some time afterwards the party of men we passed also got their lights to burn; and in both places lights burned until we all arrived safely at the upper seam.

LESSONS DERIVED.

1. In all cases of similar entombments it would be advisable, while sinking a large shaft for rescue purposes, also to sink a large bore hole at the far end of such a position. Had a 3-in. bore hole been sunk near the place of entombment of the two men a current of air would have been established, and the difficulties we had to contend with avoided.

2. The necessity under such circumstances of taking into account the amount of available air, and the number of men sent into it. If the air is limited, as in this case it was, then the number of men sent down should also be limited, and men not actually working ought to come to the upper seam, all reliefs being kept there, and sent down as required.

Here let me add that acetylene gas will burn in a percentage of CO₂ gas with air in which an oil wick light will not. Whether this fact has been proved by former experiments or not, I cannot say, but it was so in this case.

On the afternoon of February 7th I again went down the pit, and found the air in the lower seam so foul and

charged with CO_2 gas that no light would burn, even in the dumb shaft, and descent was impossible. On February 10th the water was reduced to the level of the roads, thereby allowing an air current which cleared away the island of CO_2 gas, and I travelled over that section of the pit with safety and with lights.

These facts prove also my statement that no air could enter the section where the rescue party were working unless a bore hole or other opening had been made as stated.

The first fact shows the dangers we all passed through, and establishes for all time the value of oxygen in all such cases. Had oxygen not been used, the two men would have lost their lives.

In conclusion, I should like to say:

1. That oxygen gas is an absolute necessity and a valuable adjunct to all pit plant.
2. That the men ought to be trained in its uses.
3. That its properties and uses should form a part of the examination for a manager's certificate.

A SIMPLE METHOD OF ESTIMATING AMMONIA IN THE URINE, SUITABLE FOR CLINICAL PURPOSES.

By G. C. MATHISON, M.B., B.S.MELB.,
SHARPEY SCHOLAR, UNIVERSITY COLLEGE.

A KNOWLEDGE of the amount of ammonia present in the urine has an important practical value in many conditions met with in everyday practice. Normally about 3 per cent., in disease as much as 50 per cent., of the nitrogen excreted in the urine is in the form of ammonia. In diseases associated with grave metabolic upset, particularly where gross changes take place in the functions of the liver, and in severe toxæmias such as those not infrequently seen during pregnancy, the amount of urea is usually greatly diminished and its place is taken by ammonia and allied bodies. In the condition known as acidosis the formation of acid products, such as aceto-acetic and beta-oxylbutyric acids in intermediary metabolism, necessitates the utilization of ammonia to effect their neutralization. The ammonium salts formed are excreted in the urine, and the quantity of these present, especially in its relation to the amount of urea, gives an excellent and early indication of the existence and extent of the metabolic perversion. The estimation of the organic acids excreted is a matter of very great difficulty; but since they are in combination with ammonia, the estimation of this body will afford information as to the quantity of these acids present. It is thus obvious that a simple method of estimating ammonia is greatly to be desired. It is only large quantitative changes in the output of ammonia that are clinically significant: in pathological conditions the nitrogen present as ammonia frequently constitutes 25 per cent., while it sometimes reaches 50 per cent., of the total. Thus the employment of an elaborate method of estimation in an attempt to obtain particularly accurate results is unnecessary.

The methods commonly employed¹ are either too inaccurate or too elaborate for clinical purposes. The best is probably the method of Folin,² which necessitates the employment of apparatus only found in a well-equipped laboratory, and the expenditure of several hours to perform; even this method, however carefully carried out, is not free from sources of error.

Malfatti³ has recently described a method that is admirably suited for clinical use, since it is simple and rapid, requires no special apparatus, gives consistent results, and possesses a sufficient degree of accuracy.

The method depends on the reaction that takes place when a solution of an ammonium salt is treated with formaldehyde. Combination occurs between formaldehyde and ammonia with the formation of urotropine, as shown in the equation

The acid previously combined with the ammonia is liberated, and can be titrated. The procedure is conveniently carried out as follows:

Twenty-five c.c.m. of urine are measured with a pipette into a clinical flask of about 250 c.c.m. capacity, and diluted with

about 50 c.c.m. of distilled water. Four drops of a 1 per cent. alcoholic solution of phenolphthalein are added, and decinormal sodium hydrate is run in from a burette till a definite pink colour that does not disappear on shaking is attained. The number of cubic centimetres of decinormal soda added gives the acidity of the urine. About 5 c.c.m. of commercial formalin that have been neutralized beforehand by adding an equal volume of water, a drop of phenolphthalein solution, and sufficient decinormal soda to produce a pink tinge, are now added to the urine. The pink colour at once disappears, since the acids previously combined with ammonia in the urine have been liberated.

More decinormal soda is added till the pink colour reappears. This amount of NaOH is chemically equivalent to the ammonia previously present as ammonium salts, now in combination as urotropine. The amount of nitrogen present as ammonia in the twenty-four hours' urine can readily be calculated, since 1 c.c.m. of decinormal soda is equal to 0.0017 gram of NH_3 —that is, to 0.0014 gram of nitrogen.

I have found that the accuracy of this method can be considerably increased by adding 15 grams of powdered neutral potassium oxalate to the urine and shaking for two minutes before titrating; the end point is rendered much sharper, partly owing to the precipitation of calcium, partly to a diminution of the influence of ammonium salts, both calcium and ammonium salts having a disturbing influence on the end point of the first titration.⁴

I have compared this method with Folin's, carried out under the standard conditions laid down by him, in a large number of urines. The following is a sample of the results:

Grams of Ammonia Nitrogen in 100 c.c.m. Urine.

Urine No.	Formaldehyde.		Folin.
	Without oxalate.	With oxalate.	
1	0.074	0.078	0.066
2	0.067	0.069	0.063
3	0.051	0.053	0.052
4	0.056	0.060	0.052
5	0.026	0.029	0.025

In all the urines examined the formaldehyde method gave higher results than the Folin method—usually about 15 per cent. higher. This represents about 1 per cent. of the total urinary nitrogen. What the causes of this discrepancy are cannot definitely be stated. None of the ordinary urinary constituents are affected, under the conditions of the method as described above, in such a way as to exert any influence on the titration.

Uric acid, for example, though affected by formaldehyde in the presence of excess of alkali,⁵ can be added to urine in large quantity without altering the ammonia value given by the above method.

Sorensen has shown that formaldehyde combines with the amino group of amino acids, setting free carboxyl radicals, which act as acids and may be titrated, affording a measure of the amino acids. It was found that the addition of glycocholl and several other amino acids to the urine increases the ammonia value as given by the formaldehyde method, so that possibly the difference between this and the "Folin" value represents amino acids. Whether these are present in normal urine is at present a matter of dispute, but in pathological conditions—usually those in which the ammonia output is high—large quantities of amino acids are excreted. These bodies have replaced part of the urea, and their significance clinically is similar to that of excess of ammonia. The fact that the formaldehyde method gives the sum of ammonia and amino acid value is thus rather an advantage than otherwise. If it is desired to estimate the amount of amino acids excreted in cases in which the output is high, an approximate result can be arrived at by subtracting the Folin from the formaldehyde values.

III.—THE CORRELATION OF THE UTERUS AND OVARIES.—Continued.

RESULTS OF EXPERIMENTS.

SERIES B.

Removal of Uterus and Subsequent Examination of the Ovaries.

On the whole, we have not been satisfied with the experiments we have conducted in this inquiry. We operated upon two bitches and twelve rabbits. All the animals were about 6 weeks of age at the time of operation. Unfortunately our bitches died of distemper within a few months of the hysterectomies, so that they never reached sexual maturity. We lost five of our rabbits, too, from an epidemic of pneumonia. The rest (about half) that reached sexual maturity were killed at different periods, the longest time that was allowed to elapse between the operation and the examination being eight months. In every case the uterus was removed and the Fallopian tubes as far as practicable. In several cases, when the animals were killed, it was found, however, that the whole of the Fallopian tube had not been removed. It will be understood how difficult it was to effect this in view of the small size of the animals.

In no case did we find any histological change which

corpus luteum. In Fig. 16 is seen a section of an ovary removed from a doe whose uterus had been removed eight months previously, and who had frequently been to the buck. Many sections were cut of this ovary, but nowhere could we find evidence of corpus luteum formation. Ripe follicles and degenerated follicles there were in abundance, but nowhere was there any evidence that a follicle had ruptured. The degeneration, too, of the follicles appears to be of a more cystic nature than in the normal animal. It will be noticed in Fig. 16 that the interstitial cells are as well marked as in the normal ovary. In Fig. 17 is shown a section of the ovary from another doe whose uterus had been removed five months previously. In this case also no corpora lutea can be seen, although in other respects the ovary appears normal.

Heape⁴ has produced evidence to show that the follicles in the normal rabbit's ovary do not rupture unless the doe has connexion with the buck. But in our cases the does that attained maturity had this connexion and apparently came on heat, but in spite of this there was no rupture of Graafian follicles. We must confess that we had fully anticipated that we should find marked changes in the ovary after hysterectomy in spite of the observations of others, and we based this belief on our own clinical experience and on the clinical experience of Abel, Zweifel, and others. But beyond the fact stated above—which may or may not be of importance†—we had no confirmation of our ideas. It is quite possible, however, that a much longer time must be allowed to lapse before changes become apparent, and once more we cannot refrain from saying that, in view of the structure of the rabbit's ovary, comparison with the human ovary is hardly fair. We consider, therefore, that our experiments are inconclusive in this matter, and we shall hope to return to the subject at some future time.

SERIES C.

LIGATION OF THE UTERINE CORNUA.

In this series of experiments we have made observations on (a) the nature of the uterine secretion, (b) the condition of the uterus which had undergone expansion, (c) the condition of the ovaries (in the first experiment).

I.—Ligation of the Cornua without Removal of Ovaries.

We performed a large number of these experiments, in order to collect the fluid secreted by the uterus, for exami-

Fig. 15.—Normal adult rabbit's ovary with corpus luteum. $\times 200$.

could have been held to have occurred as the result of removal of the uterus. At the same time there appeared to be the negative effect that in no case could we discover the formation of corpora lutea,⁴ or any evidence that Graafian follicles had ruptured, in spite of the fact that the animals came on heat and had connexion with the buck.

In Fig. 15 is seen a normal adult rabbit's ovary with a

It is somewhat difficult to define what is meant by "corpora lutea" in rabbits' ovaries since there is no rupture of the follicle without connexion with the buck, but we may recognize three varieties (and we include all three in this term): True and false corpora lutea and the corpus luteum of normal degeneration.

Fig. 16.—Rabbit's ovary after hysterectomy. $\times 200$.

nation and experimental purposes. Consequently we were able to make a number of observations. In all cases we used silk as the ligature material, and usually we doubly ligated each uterine cornu, although it is not necessary to tie the ovarian extremity of the horn, as no leakage occurred in those cases in which we omitted to do so.

(a) *The Nature of the Secretion.*—This we have already dealt with in Paper II.

⁴ Especially in regard to lowered calcium content producing rupture of the follicle.—See Paper II. Compare also C. J. Bond, Experiment XXV (see references).

(b) *The Condition of the Uterus which had Undergone Expansion.*—A section of such a uterus is shown in Fig. 18. One observes a more or less even distension. The endometrium is flattened and thinned from pressure, but the muscular layers do not seem to suffer. It is probable that in those cases in which the muscular layers are well developed gradual distension of the uterine cavity leads to hypertrophy. This is a point of considerable interest,

resembled that from the virgin uterus, containing less calcium salts than that obtained from a menstruating uterus. We also noticed that in its physiological effect it was not as active as that obtained from the menstruating uterus. (This will be referred to again in Paper IV.) In regard to this inactivity there was a possible source of error, in that it had been kept, sealed in glass capsules, for some little time before being used. We mention this fact

Fig. 17.—Rabbit's ovary after hysterectomy. $\times 200$.

and very suggestive of the muscular hypertrophy which occurs in pregnancy. We intend to follow the matter up further.

(c) *The Condition of the Ovaries.*—We have been unable to trace any changes in the ovaries as the result of this experiment—microscopical or macroscopical. Bond thought that there were changes, but the condition that he found is probably merely the ordinary result of Graafian degeneration, frequently to be observed in rabbits that come on

Fig. 19.—Ovary of young doe with hydrometra. $\times 200$.

though we are not ourselves convinced that it is one of any importance.

(b) In Fig. 21 is shown a section of a uterus the horns of which had been tied two and a half months previously, the ovaries having been removed at the same operation. In this particular case the rabbit had had young shortly before. Those experiments on rabbits that had not been recently pregnant gave the same results.

It will be seen from the section that a large hydrometra

Fig. 18.—Hydrometra without removal of ovaries. $\times 200$.

heat but do not have connexion. (Compare Heape, loc. cit.)

Figs. 19 and 20 are sections of young and mature ovaries respectively, removed from does in which hydrometra had been artificially produced. It will be seen that they are quite normal.

II.—Ligation of the Cornua with Synchronous Removal of the Ovaries.

(a) Fluid is freely secreted, the removal of the ovaries making no difference to the quantity. The fluid collected

Fig. 20.—Ovary from young adult rabbit with hydrometra. $\times 200$.

was formed, and that in the process of expansion the endometrium has become much thinned from pressure. It is interesting to note that the muscular layer has not become atrophied to the extent it would have done had the uterine horns not been tied when the ovaries were removed. We think that this is to be explained by the fact that the muscle fibres are called into use to resist the increasing pressure. This view is in harmony with the idea we hold that atrophy of the uterus after removal of the ovaries is primarily due to the consequent inactivity of the uterine muscle, which is, as we have already shown, the first

portion of the organ to be a subject to degenerative changes. It is important to remember that this condition of muscular atrophy recurs seasonally in a physiological manner and degree in wild rabbits.

III.—Removal of the Ovaries followed by Ligation of the Uterine Cornua at a Subsequent Date.

(a) We found that the fluid secreted in these circumstances was as copious as in the last experiment, and closely resembled that secretion in its low calcium content and physiological inactivity. (This was also, however, as in the case of that obtained in the last experiment, kept some time in sealed capsules before being used.)

(b) A typical section of one of the uteri examined is seen in Fig. 22. In this case the animal had been pregnant, and had aborted after removal of the ovaries. Twenty days later the cornua were tied. A month later the animal was killed. In every particular the section of this uterus is comparable with that seen in Fig. 21. and in marked contrast with Fig. 10.

Removal of the ovaries, therefore, whether performed previous to ligation of the cornua or synchronous with that operation, does not affect the quantity of the secretion, while it does appear to alter the chemical nature of

examined the ordinary wild rabbits were breeding. Our examination every uterus was found to be in an inactive condition, and the ovaries were all small, and contained no ripe follicles.

It is, of course, possible, that captivity was the cause of this—of the fact that none were on heat; but we incline to the view that it was—in part at least—because the presence of the buck is an exciting factor in the case of wild does in regard to the onset of genital activity early in the year. We were quite unprepared for this result of our examinations, for we hoped to get inactive uteri in the first lot and menstruating uteri in the second, in order to estimate the total calcium in the ash of each lot of uteri. We give this observation for what it may be worth. The great difference between wild animals and domestic animals in their breeding habits is at once a source of wonder and information, and enables us more than anything else to realize how intimate is the association between the genital functions and the general metabolism of the body. The experiments we have described not only indicate that there is this close connexion between the general metabolism and the genital organs, but also that there is a definite interdependence (so long known and recognized, but never defined) of each part of the

Fig. 21.—Hydrometra with synchronous removal of ovaries. $\times 200$.

it, as already indicated by the lowered calcium content and reduced physiological activity.

The histological appearances of the uteri are striking and suggestive, and readily bear the interpretation already put upon them in regard to the hypertrophy rather than atrophy of the muscular layer under these conditions.

We found also in the course of our experiments on hydrometra that unilateral ligation of a cornu does not at all interfere with pregnancy in the other cornu. One of our rabbits in which we made a unilateral hydrometra and stitched it to the abdominal parietes for satisfactory observation subsequently had two litters, both of which appeared at full time, and were reared. We thought, however, that the cyst got smaller during the pregnancies. This bears out Bond's observations as to the absence of secretion from a cornual fistula during pregnancy in the other horn. Indeed, many of our experiments here recorded confirm much of what he has stated in a recent publication. It is only right, however, to mention that our experiments were begun before his paper appeared.⁶

There is one more experiment (for the successful performance of which we are indebted to Mr. James Smith) to which we would like to allude:

One of us arranged with a keeper in Scotland to catch forty wild doe rabbits in February. Twenty of these were immediately killed and the genital organs examined. In every case the uterus was in the inactive or non-contracting state, and was flat and ribbon-like. The ovaries were small, and contained no ripe Graafian follicles. The remaining twenty rabbits were kept in captivity away from bucks for about two months, during which time two died. As far as possible the animals kept in captivity were allowed to lead a natural life, except for the presence of bucks. At the time these were killed and

Fig. 22.—Hydrometra after previous removal of ovaries.

genital apparatus—that is to say, of the uterus and ovaries.

And, finally, these experiments help us to understand the specific changes that occur in each part as the result of interference with the other, or in altered circumstances. They have, in short, enabled us to attempt to define what that specific relationship is, and in coming to our conclusions we wish to acknowledge the assistance we have received from the work of those other observers in the same field of investigation to whom we have already referred.

A CASE OF MYCOSIS FUNGOIDES IN THE PRE-MYCOTIC STAGE.

R. F., aged 65, was admitted to Dr. Calwell's wards in the Royal Victoria Hospital, Belfast, on January 2nd, 1909. Fifteen months before admission he noticed the extensor surfaces of both forearms covered with reddish scales. During the succeeding four months this scaliness spread over the whole of his body, and was accompanied by extreme pruritus. Four months previous to admission large patches of brownish pigment appeared on his trunk and extremities.

On examination his body was found to be covered with cranny, desquamating scales, and he complained bitterly of the associated pruritus. The skin had a general reddish tinge, with large areas of brown pigment irregularly deposited on trunk and limbs. The skin was also greatly thickened, especially over the extensor surfaces of the knees and elbows, where the integument hung in thick, leathery folds. The lymphatic glands in both axillae and groins were enlarged, and there was an almost complete absence of hair from the body. He complained greatly of cold, nervousness, and general weakness. The differential leucocytic count showed 8 per cent. eosinophiles, but otherwise the blood was normal.

He was detained in hospital for five weeks, and calcium lactate internally with calamine liniment locally were tried, but no improvement was observed.

The following were given as the outstanding features of the premycotic stage of mycosis fungoides in the *Journal of Dermatology*, vol. iii, No. 3:

1. Spontaneous occurrence of attacks of inflammation of the skin; practically involving the whole body, each successive attack leading to thickening of the corium and subcutaneous tissues, so that permanent, thick, tortuous folds result.
2. Loss of the skin appendages.
3. Enlargement of all the lymphatic glands.
4. Frequent febrile temperature and progressive loss of strength, terminating in death from exhaustion.

BEE STINGS AND RHEUMATISM.

The progress of the cases recorded in my note published in the *JOURNAL* of December 5th, 1908, p. 1678, has been since that date as follows:

CASE I.—A man, aged 76, tells me he has suffered not for ten, but fifteen years. He is continuing the treatment at the rate of twelve stings a week, and the pain which "left his hips and went into the thighs" changed its position to the knees on December 16th; on December 30th it returned slightly to the left hip, and on January 12th moved to the calves of both legs. He had only had fifty bees on the last date, having been shy at the pain in the commencement.

No. II still has some intercostal pain, but very much shorter in duration. She gave up the bees, but recommenced them after ten days.

No. III is coming to Birmingham again to have more bee stings, as he has been much freer from pain, which is much less, especially at night.

No. IV continues quite free from pain and is in excellent health.

The following cases are new:

No. v.—F. C., a mechanic, aged 34, suffered from sciatica for eighteen months. For four months he was under the care of a private medical man who ordered him to Droitwich, where he had the usual baths for fourteen days. He went there also for the next eight or nine week-ends, having on each occasion four baths. He returned little improved, and attended a hospital for fourteen days as an out-patient. After that for four months he was treated at the same institution by massage, and the galvanic battery, but without relief. On November 27th he commenced with twelve bee stings, which were repeated every week for six weeks. In five weeks there was marked improvement, and when I saw him last, on January 16th, he said he had been getting steadily better, so that he frequently did not know he had got sciatica. He had had, up to the last date, 100 bee stings.

No. vi.—K. H., a married woman, aged 36, had during the past three years suffered from rheumatism and arthritis in the jaws, hips, knees, feet, elbows, wrists, shoulders, and hands. The bees were applied first on December 1st, and she had twelve every week till January 4th, or sixty in all. "Results: Rheumatism nearly gone from the shoulders. Right wrists a little free. Right arm not quite set, but apparently released a little. Not so much pain generally. For the past two years there was incessant acute pain whether active or idle."

No. vii.—E. N., a single woman, aged 35, had suffered for three years and a half with rheumatoid arthritis in wrists and fingers, which are much deformed, and also in the ankles. She had been treated as an out-patient at a hospital and was an in-patient for ten weeks, when she says, she "received some relief from the rest from work." She commenced the bee stinging on November 21st, 1908, and on January 16th had had sixty-six stings. The grasp was much stronger, the wrists, fingers, and ankles more movable, stronger, and quite free from pain. Her nights, which had been frequently very bad, are much better.

No. viii.—H. D., a mechanical engineer, aged 54, was lame by a kick above the left knee when 10 years old, and had some bone removed. For the past thirteen years he has been gradually getting worse in the other leg from increasing sciatica. On January 8th and each of the following dates I applied eight

bees to the region of the sciatic nerve—for I am satisfied that the stinging is not only antitoxic, but also counter-irritant—and on the following day he told me that before stinging he had to hang on to various articles of furniture to assist his crossing the dining-room, but when he returned home, after being stung, he could do so without assistance. On January 11th his leg felt stronger and he could walk better. On January 15th he said he had less pain on leaving bed, and much better nights since January 8th, but followed by considerable pain in the day. He was better on January 15th and his nights were still good. Walking did not seem so firm. There was a large, circular, inflamed patch over the trochanter. The last application of bees was followed by severe inflammation along the thigh. On January 19th the leg was not so strong, and there was increased pain. On January 22nd he reported that he had had more pain in the day, but the nights were very much better. On January 25th the still severe, particularly in the femur. On January 29th pain followed in the right hip joint. On February 2nd there was great stiffness in thigh and knee-joint, and he was compelled to walk more slowly. On February 5th there was no improvement; but he was no worse. This gentleman seems to be losing heart, but, after thirteen years, cure cannot be expected under a month, and after only 100 bees have been used.

He is continuing the treatment. As to my own case, up to January 22nd my progress was most satisfactory. I continued to apply two lots of bees a week, and in all 271 to that date. I had slight twinges of muscular rheumatism of not more than a few minutes' duration, for which reason I persevered with the treatment. But on that day I contracted a chill, and suffered at night some pain in the glutei and right sciatic nerve. I at once put on eleven bees, and slept well, the pain next morning being much easier, and permitting me to work. On January 23rd, after a long harassing day, I got to bed tired at 10 p.m., and applied fifteen bees, and on January 24th only had slight pain in the glutei, none in the sciatic. I made a necropsy for the coroner at 6.30 p.m., in a fireless mortuary, with a glass roof, the temperature being below freezing. On January 25th I attended the inquest in a court with mercury at 70°; the external temperature being 25°. I applied twelve bees on January 24th, and eight on the following day. On January 26th I had great pain in the glutei on walking, and put on twelve bees at night. Next morning I was much easier, with only slight pain towards night, and had eight bees. On January 28th I still had pain in the glutei, and on January 29th this was increased on walking. I applied fourteen bees, and was better on January 30th, but still had some difficulty in walking. On Sunday, January 31st, I rested in bed all day, and applied eight bees at night. On February 1st to 7th the pain varied. On February 3rd and 4th there was much pain after walking, and I applied in six days forty-five bees. On February 20th I was entirely free from acute pain, but still continue the stinging. I am taking no other medicine, and, but for occasional transient pain, feel very it, and have, as one of my old ladies says, a very "avaricious appetite."

I regret to hear from several medical men that the bee-keepers, both here and in Scotland, will not take bees from their hives during hibernation, although the Editors of the *British Bee Journal*, 8, Henrietta Street, Covent Garden, stated, in reply to a letter from me in their issue of January 21st, "It is well known that there would be little or no trouble in obtaining a few live bees at any season of the year from any expert who could have access to a hive." I have ascertained that if the bees are put in a properly ventilated box, covered with cotton-wool, and enclosed in a second box, also ventilated, they will stand a long journey by post. They should at once be placed in a very warm position. I made a hole in the rim of a halfpenny tin plate, allowing the upright of an iron retort-stand to pass through it; the plate rests on the iron ring, or is fastened with wire to make it more secure. A spirit lamp with $\frac{1}{2}$ -in. flame is placed beneath, and the ring lowered to 4 in. or 5 in. from the flame. A cheap thermometer is wired to the top of the upright, the bulb resting on the plate. By this means a temperature of 76° can easily be maintained, and the bees, if supplied with candy, as they ought to be by the vendor, require only a few drops of water on their food each day, and will keep well for several days. The spirit lamp should be filled in the evening, or the bees may be found dead from cold in the morning. My bees are quite lively at the end of four days.

I have been asked frequently as to the pain of stinging. After the first three stings on myself, I find that the intensity of the pain is much less lasting than at first—in fact, is over in half an hour at the most. Some of the bees seem to cause greater pain than others, but I think this may be explained by a larger cutaneous nerve being wounded by the sting. I hope that shortly your readers will have, from his own pen, the experience of another Birmingham practitioner, who tells me he has found great relief to old-standing sciatica from this treatment.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

YORKSHIRE BRANCH: LEEDS DIVISION.

Leeds, Tuesday, March 2nd, 1909.

T. WARDEOP GRIFFITH, M.D., F.R.C.P., in the Chair.

Venous Pulse in Neck.—Dr. GRIFFITH gave a description of the venous pulse in the neck by diagrams on the slate, and a demonstration of pulse tracings in cardiac arrhythmia by means of the epidiascope. Normally three waves could be made out in a tracing from the jugular vein. On comparing such a tracing with a radial artery tracing taken simultaneously, the second wave was found to occur $\frac{1}{2}$ second before the radial wave, and, as was known, the carotid pulse preceded the radial by $\frac{1}{2}$ second, it might be assumed the second venous wave was due to the impulse communicated from the arteries in the neck; the first wave must be due to the auricular contraction which came just before, while the third wave was due to the blood held up in the auricle and veins during the closure of the tricuspid valves. The three waves were found when the heart rhythm was regular, and acting in obedience to a stimulus starting at the sinus, and passing along the *a-v* bundle to the auricle and ventricle. Tracings from a case of mitral disease showed remarkable alterations of rhythm; the jugular pulse, after a sudden rapid irregular action of the heart, lost the auricular wave, and a steep wave synchronous with the ventricular systole appeared. This new wave was caused by an impulse sent through the tricuspid valve and the auricle to the jugular vein by the ventricular contraction. In order to effect this the auricles and the ventricles must contract together. In such a condition the stimulus for contraction was assumed to start at the node in the *a-v* bundle, and cause simultaneous action of the auricles and ventricles; this was named "nodal rhythm." The action of the *a-v* bundle might be impaired by disease, or the bundle might be weak and inactive. Disease might affect the sino-auricular junction and produce arrhythmia, or it might be so situated that the stimulus did not get beyond the auricle. In such a case the ventricle might beat with a rhythm of its own, and much slower than the auricle. Such impaired conductivity of the bundle tended to heart-block, and might sometimes be improved by the administration of atropine, while digitalis was contraindicated, for partial heart-block might be caused by digitalis.

Dr. GRIFFITH also showed specimens of disease of the heart.

Fracture of Ribs.—Dr. ALLAN read notes of cases of extensive fracture of ribs. Two men, one aged 56 the other 61, fell into the same clay pit, a distance of 50 ft.; both lived about two days, and in both the injuries were confined to the bones of the thorax. In the younger man all the right ribs were fractured, and all the left except the eleventh and twelfth; the other man had the fifth, sixth, eighth, ninth, eleventh, and twelfth right ribs broken, and all the left except the eleventh and twelfth; this man also had a fracture of the sternum. A man aged 81 and a woman aged 66 fell from windows a distance of 25 ft. The former was killed at once, the latter lived a few hours. In the man all the right ribs were fractured except the first, eleventh, and twelfth, and all the left except the first. In the woman, the second, third, fourth, fifth, and sixth right ribs were fractured and all the left ribs; here there were fractures of the pelvis and left forearm, while in the old man only ribs were fractured. A man aged 67 and another aged 52 had fracture of ribs, the former of six ribs the latter of seven ribs, due to fall down flights of steps, and in neither had the condition been diagnosed before autopsy. There were no other injuries.

Specimens.—Dr. ALLAN also showed various pathological specimens, and a lad with general ichthyosis.

Twenty members were present. Tea was provided by the Dean of the Medical School, Professor Grünbaum, to whose courtesy the Division is indebted for permission to meet in the University buildings.

Reports of Societies.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Thursday, March 11th, 1909.

W. H. H. JESSOP, F.R.C.S., Vice-President, in the Chair.

Congenital Anterior Staphyloma.

Mr. E. TREACHER COLLINS, in a paper on congenital anterior staphyloma, described the case of a child born with an opaque, vascular, staphylomatous cornea; it had never any discharge from the eye. When 15 months old he performed a Mules's eversion upon it, and subsequently made a pathological examination of the elliptical piece removed from the front of the eye. It was found that Descemet's membrane and the ligamentum pectinatum were absent, there was no stroma to the iris, and the lens was also malformed. Most cases of congenital anterior staphyloma had been attributed to intrauterine ulceration. The speaker thought that a case in which there was complete absence of Descemet's membrane and the ligamentum pectinatum could not be accounted for by ulceration, and must be attributed to some developmental defect. Possibly there had been a failure in the differentiation of the mesoblast which intrudes between the lens vesicle and the surface epiblast into its several layers. Normally there developed from it the substantia propria of the cornea, Descemet's membrane, its lining endothelium, and the antero-fibrovascular sheath of the lens. From this latter the fetal lens largely received its nutrient supply, and the stroma of the iris was to a great extent formed. A failure in the differentiation of the several structures or atypical development of the intruding mesoblast might, as in the case under consideration, lead to a vascularized, thickened, fibrous mass in place of the substantia propria, an absence of Descemet's membrane, of the stroma of the iris, and a malformed lens. He concluded by referring to several other malformed eyes, in which he had found defects in development of Descemet's membrane or the ligamentum pectinatum of a less extensive character.

The paper was discussed by Mr. PARSONS and Mr. G. COATS, who failed to agree with all that Mr. Collins had advanced.

Hereditary Cancer.

Mr. E. NETTLESHIP contributed seven new pedigrees of hereditary cataract: (1) 24 cases of lamellar cataract in four generations; (2) and (3) coralliform cataract, one of them containing 20 cases, in four generations; (4), (5), (6), and (7) pedigrees of senile and presenile (or juvenile) cataract in from two to four generations, some of them illustrating "anticipation," that is, the occurrence of disease at an earlier age in the younger generation. Two of the pedigrees showed the introduction of a second heritable disease from an outside non-cataractous stock, goitre in one instance, insanity in the other.

Temporary Colour Blindness.

Dr. F. W. BRIDGEMAN and Mr. C. DEVEREUX MARSHALL submitted a paper on so-called artificially produced temporary colour blindness. They stated that Professor BURN, of Oxford, had read a paper before the Royal Society, which was published in the *Philosophical Transactions* in 1898, giving the results of his experiments, in which he split up direct solar light with a spectroscope, and then collected the rays of the individual colours with a convex lens, and saturated his own eye with any desired colour. He then examined a spectroscope illuminated with diffuse daylight, and stated his results. He found that he could produce temporary colour blindness to any colour in this way. His most important point was that by saturation with light at the "D" line, red and green blindness supervened, and these colours could not be perceived, and this he held to support the complex nature of yellow light, the Young-Helmholtz theory of colour perception. The authors criticized these experiments. They thought that if direct sunlight were focussed in the retina, not only temporary, but probably permanent, blindness might be produced, and anyhow the eye would be incapable, after much treatment, of making accurate observations on a feebly illuminated spectrum. They produced fatigue in their

own eyes with a sodium light, and then found that yellow and orange became obliterated, and that red and green met in the spectrum, and that there was no diminution of those two colours. Other experiments were repeated with different colours, and in most of them they disagreed with Professor Burch's results, which they held were due to faulty methods of conducting the experiments. These facts were, they contended, only explicable on the psycho-physical theory of colour vision (Etridge-Green's theory).

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

Tuesday, March 9th, 1909.

MR. WARRINGTON HAWARD, President, in the Chair.

Urachal Cyst.

MR. ALBAN DORAN read a paper on a urachal cyst, simulating appendicular abscess. His patient, a girl aged 17, had an imperfectly formed genital tract; the uterus was bicornuate, with only the right corn functioning. After describing his procedure in this and in a former case, the author referred to the studies of Wutz and Binnie on the urachus: to the vesico-urachal valve; and to the question of a meso-urachus described by Keith, Thane, and Binnie. He recommended the classification of morbid dilatations into (1) urachal fistulae, (2) primary cystic fistulae, (3) pure urachal cysts, and (4) secondary cystic fistulae developed from pure cysts which have acquired communication with the bladder, or the surface at the umbilicus. He mentioned the spurious cases of Hoffman and Lawson Tait, which were really instances of encysted dropsy or tuberculous peritonitis. He thought there was certainly some connexion between the anomaly in the urachus and the arrested development of Müller's ducts. The asymmetry observed in his case, in which it had led to a diagnosis of appendix abscess, had been noted by other surgeons, and detected in incipient cysts by pathologists. Suppuration in a urachal cyst was by no means uncommon, and peritonitis around them quite common.

Mr. F. S. EVE described a case, and exhibited the specimen, of a large cystic sarcoma of the urachus. The patient was a man aged 33. When seen he was complaining of painful micturition, and was having rigors. Something like five pints of blood, dark and obviously infected, was let out; the bladder was opened in removing the mass, which was sessile, upon it. The patient died on the fourth day. In Wieser's collection of 89 cases it was notable that suppuration occurred in at least a third. Operative difficulties frequently rendered complete removal impossible. He interpreted the anterior peritoneal covering of his specimen as due to the expansion during its growth of a meso-urachus, or to involution of the peritoneum as it grew upwards and backwards. He thought it remarkable how seldom a surgeon came across remnants of the urachus in opening the abdomen. He had only seen one other case of urachal cyst, and that was brought from Clare market; it was attached to a pig's bladder.

Mr. W. G. SPENCER asked where the sepsis came from; did it reach by way of the bladder or from the intestine?

Mr. DORAN, in his reply, said that intestine was nearly always adherent at the back of these cysts, and hence infection was generally from this source.

Continuous Suction.

Mr. HERBERT T. HERRING demonstrated a portable apparatus for the employment of continuous suction in surgery. It consisted of a rotary pump, electrically driven, acting by means of thick-walled tubing through a "receiver," upon the wound or cavity under treatment. The mechanism was capable of utilization for irrigation or for the suction of viscid substances such as blood.

CLINICAL SECTION.

Friday, March 12th, 1909.

SIR THOMAS BARLOW, M.D., President, in the Chair.

Nerve Anastomosis.

MR. A. H. TUBBY showed (1) a man, aged 19, admitted to Westminster Hospital for complete extra-cranial paralysis of the branches of the facial nerve, resulting from an operation wound. Facio-hypoglossal anastomosis was

effected, and improvement in the orbicularis was noted a week later. In fourteen days the left angle of the mouth began to move. Progress continued until the whole left side of the face recovered. When shown there was only a little drooping of the left side of the mouth and very slight associated movements of the tongue and face. (2) A boy, aged 9, admitted to Westminster Hospital in October, 1905, for infantile paralytic talipes calcaneus of seven years' duration. The nerves to the gastrocnemius and soleus were separated from the internal popliteal and implanted on to the external popliteal trunk. The case slowly improved, and, though full recovery of power was not obtained, there was great amelioration of the original condition. (3) A man admitted with total paralysis of the right arm. He had been stunned on board ship, and at a hospital in New York was trephined as suffering from meningeal haemorrhage, without benefit to the paralysis. On admission under Mr. Tubby, the brachial plexus was dissected out from the spine to the lower part of the axilla. The upper part was lost in a dense mass of fibrous tissue, and in the fifth nerve was found a fibromatoma. This was excised and the distal trunk of the fifth cord inserted into the sixth on February 12th, 1906. Recovery of power began two years after the operation, and when shown the patient had a well-developed biceps, could flex the forearm well, and the deltoid action was returning. Sensation was still absent over the greater part of the limb, but was spreading down from the upper and outer part of the arm, and had nearly reached the middle of the outer surface. Further improvement was expected.

Mr. C. H. FARGE showed (1) a girl aged 10 in whom complete facial paralysis followed a mastoid operation, otorrhoea continuing. A radical mastoid operation was performed at the Evelina Hospital, and at the same time the vertical portion of the facial nerve was divided as high as possible, and its distal end grafted into the side of the undivided hypoglossal exposed by continuing the mastoid incision downwards into the neck. Electrical treatment was resumed, and within a few weeks the left facial muscles regained their tone and the power of reflex blinking returned. (2) A case of inflammatory facial paralysis treated by anastomosis between the facial and the trapezial portion of the spinal accessory; movements of the left side of the face were best carried out when the left arm was raised.

Mr. C. M. PAGE (for Mr. BALLANCE): A woman, aged 54, in whom, two months after a comminuted fracture dislocation of the upper end of the humerus, the internal and posterior branches of the brachial plexus were sutured, with the result that there was recovery of the function of the musculo-spiral nerve and of sensation in the distribution of the ulnar.

Dr. R. F. KENNEDY (for Mr. SARGENT) showed a case of successful nerve grafting of the fifth nerve of the brachial plexus into the sixth.

Mr. JAMES SHERRIN showed ten patients illustrating the results of treatment of various nerve injuries. They included (1) a man aged 36 who had injured the median nerve below the point at which its palmar cutaneous branch is given off, probably by a fall on the outstretched palm; trophic blisters resulted. (2) A man aged 24 who had sustained an incised wound of the wrist on October 28th, 1903, dividing the ulnar nerve below the point at which its dorsal branch is given off. Primary suture was performed the same day, and he was discharged to the out-patient department on November 18th, with the typical sensory loss. By February 11th, 1909, the loss of sensibility to prick had disappeared, but no change had taken place in the area of loss to light touch.

Miscellaneous Cases.

Among the other cases shown were the following:

Major G. C. SPENCER, R.A.M.C.: A case of *Sarcoma treated by Coley's fluid*. The patient was a man aged 33, who in August, 1906, had a large growth in the lower part of the abdominal wall, infiltrating the recti, attached to the pubic symphysis, and extending down in front of the bladder so that it could be felt per rectum. Since the end of March, 1907, he had not had any further treatment; the tumour had completely disappeared, and he had continued in perfect health.

Mr. LAWRIE MCGAVIN: A case of *Perineal hernia* in a woman aged 36. When the hernia was reduced, a gap

admitting two fingers could be felt in the central portion of the levator ani muscle.

Mr. STANLEY BOYD described a similar case in which the protrusion was found to contain fat.

Mr. A. E. BARKER also recalled a case of corresponding appearance which on operation turned out to be a lipoma.

Dr. A. E. WYNTER: Case of ascites cured by permanent drainage through the femoral ring.

SECTION OF ANAESTHETICS.

At a meeting on March 5th, Mr. RICHARD GILL, President, in the chair, Dr. DUDLEY BUXTON, dealing with the *Treatment of shock during anaesthesia*, said that the theory that the production of very profound narcosis abrogated shock had been proved by experiment to be wholly fallacious. If, on the other hand, the narcosis stopped short of the third degree—that is, the stage of anaesthesia—the higher centres, though dulled, were not wholly unresponsive of impulses, and dangerous reflexes might occur, the patient being liable to fatal syncope. Once the third degree was obtained and the anaesthetic evenly distributed throughout the tissues, the patient was comparatively safe, and the quantity of anaesthetic required subsequently was much less. The deep reflexes, such as those resulting from insult to sympathetic nerves and plexuses, could not be prevented by any degree of narcosis; they could not be abolished until life was extinct. It had been shown that these reflexes, acting upon the vasomotor centres, the heart, and the respiration, were dangerous in proportion to the depth of narcosis after the stage of anaesthesia was established. Treatment lay rather in prevention. The hygiene of the patient (preparation extending over several days), avoidance of violent purging or enemata given just before the operation, judicious feeding, warmth, attention to posture, and the use of regulating apparatus permitting the anaesthetist to control both the strength of the vapour and the quantity of the anaesthetic given were of the greatest importance. Oxygen should be given *pari passu* with the anaesthetic, and for nervous persons and those who were unable to sleep the employment of the morphine-scopolamine method was valuable, as it lessened the amount of anaesthetic required. Other alkaloids were less useful. Dr. SILK considered the long starvation often used before and after anaesthetics an important factor in producing shock. He ordered nutrient enemata to be given before operations in cases where shock seemed likely to be very severe. Once shock was established drugs were useless. Mr. LOCKHART MUMFERY thought the drug of the future in cases of anaesthesia shock was likely to be the infundibular portion of the pituitary gland. Morphine was valuable beforehand, at least in animals when anaesthetized by ether. Dr. BLUMFELD said the condition of the reflexes was helpful in distinguishing between surgical and narcosis shock. At the end of a long operation, such as that for excision of the tongue, the degree of shock, with pallor, was often extreme, but the brisk corneal reflex showed the low vitality was not due to the narcosis. Dr. BUXTON, in reply, said that cases in which a patient left the operation table in an apparently very favourable condition, but a few hours afterwards was the subject of extreme shock, were due to change of posture, and partly also to a fall of temperature on going from a hot theatre to a cold room. As for a routine treatment of severe collapse with failure of the respiration and circulation, he advised that the anaesthetic should be stopped, the patient inverted, the mouth opened with a gag, and Laborde's method of rhythmic tongue traction practised while oxygen was administered. If further treatment be required, artificial respiration by Howard's method should be performed, and saline solution infused by someone else while the anaesthetist was thus employed.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

Friday, February 19th, 1909.

SETON F. PRINGLE, F.R.C.S.I., in the Chair.

Oesophageal Diverticulum.

Mr. WILLIAM TAYLOR read notes of a case of oesophageal diverticulum, which he had removed from a gentleman in June, 1908.

The patient was 54 years of age, and his symptoms dated back for about twenty years. The symptoms had been gradu-

ally getting worse. Food was usually regurgitated into the mouth just as it had been eaten, sometimes almost immediately, at other times after several hours. Not infrequently a portion of the previous night's supper was regurgitated next morning while in the bath. Pills taken at night were frequently regurgitated unchanged next morning. A feeling of fullness and discomfort after eating was generally referred by the patient to the right side of the neck, about the level of the hyoid bone. Attempts to pass bougies failed, their passage being arrested about nine inches from the teeth; but their passage seemed to be arrested more from spasm of the oesophagus than from encountering any other source of obstruction. There was no swelling to be detected on inspection of the neck. [A radiogram of the pouch filled with bismuth food was taken by Dr. Watson and shown, as well as the pouch itself. Through the "screen" before the photograph was taken, each bolus of food the patient attempted to swallow was seen passing into the pouch.] The pouch took its origin from the left side of the oesophagus just at its junction with the pharynx, and passed downwards behind the oesophagus, to terminate at a point just below the suprasternal notch. The diverticulum was removed through an incision extending from the hyoid bone along the anterior border of the left sternomastoid muscle to the sterno-clavicular articulation. The anterior belly of the omohyoid muscle and the superior thyroid vessels were divided. The lateral lobe of the thyroid gland, which was considerably enlarged, was displaced, after which the diverticulum was readily seen and withdrawn, there being no adhesions. Two small intestinal clamps were applied, and the diverticulum removed by dividing between them. The opening into the oesophagus was closed by three rows of fine silk sutures. A small tube was passed from the centre of the wound in the neck down to the region of the sutured oesophagus, and a piece of gauze loosely packed around it. About three-quarters of the neck wound was closed. The wound healed by first intention, except where the drainage had been applied, but even that was healed up by the end of twelve days. There was never at any time any sign of leakage from the oesophagus. All liquids by the mouth were withheld for four days. Rectal salines, with raw meat juice, were administered every six hours. Nourishment was given by the mouth on the eighth day, and gradually increased in amount and in consistency until a lamb chop was easily partaken of on the sixteenth day. The patient was now in perfect health, and had no difficulty in swallowing.

Mr. TAYLOR then briefly discussed the literature of the subject. After remarks by the CHAIRMAN,

Dr. MAGEE FINNY said the patient was under his observation for some years, and as far back as 1903 it was thought he had a pouch about his throat. It seemed reflexly to produce nervous irritation and dyspeptic phenomena. At his suggestion, Dr. Watson tried a meal of bread and milk for making a radiograph, and obtained excellent results. The same method had been tried on a patient approaching 80 years of age, and the radiograph which he exhibited showed a pouch corresponding to that in the former case. A later picture showed a lateral increase, and he would have another one taken shortly. They gave her the same mixture as Mr. Taylor used, and they could see it on the screen catching in the pouch and slipping down behind it.

Dr. McVITTIE referred to a case of dilatation of the oesophagus, brought about by spasm, in which the patient was dying of starvation. By the use of Russell's oesophageal stricture dilator, which he exhibited, the patient was completely cured.

Mr. L. G. GUNN said he had a case which seemed an ordinary case of carcinoma of the oesophagus. He did a gastrostomy, and did not think the patient would live long. Thirteen months afterwards he was looking well and had put on weight. He then thought there was a diverticulum obstructing the gullet. Dr. Woods examined the case with the oesophagoscope, and snipped away a small portion of the stricture, which proved to be a carcinoma.

Mr. R. A. STONEY mentioned a case in which the diagnosis lay between malignant disease and some simple stricture of a syphilitic nature. He opened the stomach, which was small and adherent, and fed the patient with a tube from the mouth to the stomach. Later he had to do a duodenostomy. He subsequently lost sight of the case.

Mr. TAYLOR, in reply, said he had not passed a bougie since the operation was done. Oesophageal pouches of a pressure type were met with always at the junction of the pharynx and oesophagus, and he was convinced that unless in extreme cases, the shadows in a radiograph would not extend below the pericardium.

Suprapubic Prostatectomy.

Mr. L. G. GUNN read a paper on complications following on suprapubic prostatectomy. He mentioned especially fistula, impotence, persistent cystitis, formation of stone,

persistence of some frequency of micturition, impaired power of the compressor urethrae muscle, and uraemia.

The CHAIRMAN said a fistula would close rapidly, but as soon as the catheter was taken out the scar tissue would re-contract. For a few days after operation he generally used suction apparatus. He had come to look on biccough in a prostatectomy case as a sure precursor of death.

Mr. WM. TAYLOR had recently been thinking whether they were not foolish in sticking to the suprapubic method, and not removing the prostate by the perineal route. Mr. Young's statistics showed 110 cases done in succession without a single death, and in 146 cases there was only one death. His own mortality was 8 per cent. to 10 per cent. He looked on the use of scissors as more or less unsurgical, even under one's eye, and to use them blindly did not appeal to him. Among the complications following the operation he had seen senile gangrene, arising, he believed, from a weak heart. He had also seen pelvic cellulitis follow, and he had seen a patient die apparently of haemorrhage and shock. He had found that cases in which he did not use suction apparatus did as satisfactorily as the ones in which suction was required. He now used nothing but a pad of wool, and the results were satisfactory. He looked on biccough as a sign of uraemia, and consequently a fatal omen.

Mr. GUNN, in reply, said it was hardly fair to take the statistics of one man, who was an expert at an operation and selected his cases carefully. American statistics were not so good as the general English statistics, and impotence and troubles of a similar kind must be more frequent after the perineal than after the suprapubic operation. He thought it was better surgery to pass a curved scissors and cut through the sutures, than to drag them with the finger. In two cases of Bottini's operation which he had seen the results were completely satisfactory.

LIVERPOOL MEDICAL INSTITUTION.

Thursday, February 25th, 1909.

T. H. BICKERTON, M.R.C.S., L.R.C.P., President, in the Chair.

The late Professor Hamilton.

THE PRESIDENT referred to the loss accruing to the institution by the recent death of Professor D. J. Hamilton of Aberdeen, Drs. G. E. Walker, J. Tawse Nisbet, of Liverpool, and Dr. H. W. King of Chester, and expressed sympathy with their families.

Congenital Recesses of Lower Lip.

Mr. R. C. DEN read a note on three cases of congenital recesses of the lower lip. The condition in each case was associated with double harelip and cleft palate. No family histories of congenital deformities could be ascertained, nor were any other children of the families affected.

CASE I.—Two symmetrically-placed recesses were present on either side of the middle line of the lower lip, which was thickened and everted. From them sinuses ran downwards in the substance of the lower lip, ending blindly under the mucous membrane on its inner aspect. The sinuses discharged a mucous secretion.

CASE II.—A similar condition was present, but with in addition papillae at the orifices of the sinuses. Movements of protrusion and retraction were seen in the papillae.

CASE III.—Most unusual, only one similar having been previously reported. Instead of two sinuses there was present a single slot-like cavity in the lower lip 1 in. in length and 3 in. in depth. This child also showed a deformity consisting of a fold of mucous membrane passing from the inner aspect of the lower lip close to the angle of the mouth on either side to be attached to the alveolar margin of the upper jaw. Misplaced testis and torsion of the penis were also present in this case.

Mr. DEN reviewed the various theories which had been advanced to explain the presence of congenital diseases of the lower lip. None of them would adequately account for the mode of origin of the three different types of the deformity which had been met with. The condition was a rare one, only 38 cases having been previously reported. The note was illustrated by lantern slides.

Mr. FRANK JEANS mentioned a case of congenital depressions, fistulae, in the helix. In the case of the auricle these "potential dermoids" had a definite developmental explanation.

The paper was also discussed by Mr. R. W. MURRAY and Dr. BLAIR BELL.

Spontaneous Rupture of Cyst-Adenomatous Ovarian Tumours.

Dr. BRIGGS read a paper on the spontaneous rupture of cyst-adenomatous ovarian tumours, in which he urged (1) that the primary cause of cyst rupture in cases of ovarian cyst-adenoma was tumour degeneration (necrosis); (2) that the rarity of cyst rupture in relation to the frequency of tumour degeneration was not inconsistent with the adequate vascular compensation almost invariably supplied by adhesions to the degenerated tumour; and (3) that these adhesions were simply reparative and not, as generally stated, the result of peritonitis. The innocent leakage through attenuated and thin cyst walls as a common and normal occurrence was excluded from the rare rupture; on the absence of clinical manifestations in the former and on their presence in the latter was based a working distinction. Cyst rupture as an appreciable clinical and pathological complication was one of the accidents in a case of an ovarian cystic tumour, and, just as in the case of accidental haemorrhage during pregnancy, trauma or violence in the history of its causation was almost invariably wanting. From the earlier and darker days of ovariectomy the records of sixty-six and eighty tapplings of an ovarian cyst left no doubt as to the healing power of the normal cyst wall. Dr. Briggs quoted from Meredith and Spencer Wells evidence as to the vital activity and resistance of the peritoneum and to the absence of adhesions after tapping. Where there were neither infective organisms nor loose particles of growth capable of implantation, he argued that intraperitoneal cyst rupture—at the time unattended by serious haemorrhage—was of itself a harmless, or almost harmless, pathological process. On the other hand, degeneration of the cyst produced a permanent opening and a continuous dribble of cyst contents without any barrier of defence, such as was provided by the haematocele sac around a chronic tubal drip in a case of tubal mole. Where adhesions were universal around both innocent and malignant tumours, and after torsion of the pedicle, hydro-peritoneum was invariably absent, and rupture was counteracted. Dr. Briggs narrated four cases of cyst rupture which occurred in his own practice, and submitted the following brief analysis from them:—In non-malignant cyst-adenomata the clinical manifestations were (a) of tumour degeneration: (1) impairment of health disproportionate to the size of the tumour, (2) abdominal pain, (3) variable distension of the abdomen, (4) irritability of the bladder, (5) irregular menstruation subject to the usual modifications of pregnancy, lactation, and the climacteric; (b) of rupture of the cyst: acute pain, recurrent pain, vomiting, the accumulation at a variable rate of free fluid in the abdomen. The diagnosis of cyst rupture by free intraperitoneal fluid could only be (1) positive when the partially filled cyst could be felt or when the previously firm cyst had completely collapsed; (2) presumptive when the clinical manifestations of degeneration and rupture had been obtained; and (3) occasionally and exceptionally when the free fluid was small in quantity and the rupture minute—both might escape detection before and during the operation of ovariectomy. The modern preference for removal of the tumour entire, if practicable, accounted for a long incision in Case iv, whereby both the 20 oz. of free intraperitoneal mucoid fluid and the dribble through the small aperture of rupture were exposed to view. The teaching of Matthews Duncan that, although the diagnosis of an ovarian tumour approached practical certainty, it was not one of scientific precision, applied also to the recognition of complications. The ovarian tumours of small size and the largest of only moderate size in the author's series of ruptured cysts had impaired the health of the patients to extents unusual for the size of each growth. Not one was malignant. The general peritoneum, so far as it was visible, was changed. Only in one—Case i—in which it was injected and thickened, but not shredded. Finally, Dr. Briggs compared the mechanical influence, the loss of fluid, and the degenerative changes in ovarian growths to their respective effects upon the general nutrition of the patient. He argued that the benefits the patient often experienced during temporary recumbent rest were more consistent with degenerative changes than with progressive tumour growth in cases where inflammatory complications were absent.

The paper was illustrated with lantern slides and specimens.

The paper was discussed by Dr. BLAIR BELL. He had operated on two cases, and he thought diagnosis should be easy and prognosis good. He regarded it as a rare condition. Degeneration of the cyst wall, traumatism, or violent exertion might produce it.

(Continued from p. 723.)

Kissing the Book.

Dr. F. W. LOWNDES read a paper on Kissing the Book. He gave personal recollections of forty-three years' experience in various judicial courts. He gave instances of the insanitary and dangerous nature of the English method of taking the oath, which had been clearly proved to have caused disease in two cases, while this was only an infinitesimal proportion of the real number, which it would be very difficult to trace. He urged the abolition of the use of the "Book" and the substitution of the uplifted hand. While discussing the paper the PRESIDENT proposed the following resolution:

"That this meeting is of the opinion that the custom of kissing the Book on taking an oath is insanitary and dangerous and should be abolished, and the form of administering the oath with uplifted hand be adopted."

The resolution was seconded by Mr. R. W. MURRAY, and carried unanimously.

The paper was also discussed by Drs. S. GILL, T. R. READSHAW, F. BARENDT, A. G. GULLAN, SULLIVAN, W. B. WARRINGTON, and Mr. DAMER HARRISON.

Dr. LOWNDES replied.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—At a meeting on March 3rd, Dr. P. BOOBYER, President, in the chair, Dr. C. H. CATTLE read a paper on a case of *Landry's paralysis*. The patient was a colliery banksman, aged 23, and had taken alcohol to excess, as well as sat in wet clothes a week previous to the onset of the disease. This began with muscular pains, then he turned cold, sick, and dizzy, and complained of numbness at the tips of the fingers of both hands. The arms were next affected, and after them the legs and trunk. Then the eyelids and mouth muscles became weak; there was a little headache and a slight cough. The pupils were normal and the temperature practically normal throughout. The muscles were found to be weak or paralysed in whole groups, though not wasted. There was no reaction of degeneration, the reflexes were abolished, but everywhere sensation was normal. The muscles were extremely tender when grasped, and passive movements of the limbs were very painful. The bladder and rectum were not affected, and no bedsores occurred, although he was in bed continuously for six months. For a time the intercostal muscles were entirely paralysed, so that there was imminent danger of respiratory failure. Treatment resolved itself into strychnine and belladonna internally, and then strychnine alternately with sodium salicylate. Eventually he recovered sufficiently to be moved to an infirmary, where he now looked plump and well nourished, and could get about pretty comfortably with the aid of a wheeled chair. The paper was discussed by the PRESIDENT, Drs. R. WOOD (Ilkeston), F. H. JACOB, A. J. SHARP, and B. R. B. THURMAN. Dr. CATTLE, replying, pointed out that the clinical type known as "Landry's paralysis" comprised a group of symptoms which might have a pathological basis varying in different cases. The earliest symptoms were sensory and were succeeded by progressive loss of muscular power, usually beginning at the feet and spreading upwards. There was no marked anaesthesia till a later stage, and death usually occurred in one to three or four weeks from the onset. As Landry himself had pointed out, and as had been recognized by the late Dr. Ross, the march of the disease was sometimes centripetal rather than centrifugal. In this case there was some doubt whether the lesions were in the spinal cord or the peripheral nerves; it was certain, however, that the symptoms were not due to rapidly ascending myelitis. As the action of the poison was undoubtedly selective of the motor nerve fibres, the tenderness of the muscles was well accounted for by interstitial neuritis causing irritative and pressure changes in the sensory fibres adjacent to the motor ones. Dr. CATTLE also showed a printer, aged 26, the subject of *Peripheral neuritis* of uncertain origin

affecting the lower limbs, and now recovering under galvanic treatment, and, jointly with Dr. A. C. REID, showed (1) a man, aged 39, the subject of *Spinal syphilis*, partly asymmetrical and to a great degree permanent in its results. This case also bore some resemblance to syringomyelia, as Dr. Reid demonstrated. (2) A man of 62, exemplifying the later effects of syphilis in the shape of nuclear cerebral lesions, internal and external ophthalmoplegia, and neuritis of one leg.

HARVEIAN SOCIETY.—At a meeting held on February 18th, Dr. GRAHAM LITTLE read a paper on *Ionisation in the treatment of skin diseases*. Cases of lupus vulgaris, lupus erythematosus, rodent ulcer, epithelioma, and pigmented, flat, senile warts, had been treated with zinc ions by means of a galvanic battery of twenty cells; 6 to 10 milliampères had been employed, most patients easily tolerating 7 milliampères. The positive pole had been connected with a chemically pure zinc electrode, covered with four to five thicknesses of gauze, sterilized by boiling, soaked in a 2 per cent. solution of zinc sulphate. The currents should be introduced gradually, and the electrode pressed firmly on the skin; if this were indurated, salicylic plaster, 25 per cent., was previously applied for several days. Each treatment lasted ten to twenty-five minutes; no severe pain had been caused. In a case of lupus vulgaris, in a delicate woman, a preliminary subcutaneous injection of cocaine had been useful in checking pain. In rodent ulcer, especially of the ulcerative stage, the treatment had succeeded admirably in at least four cases, in which x rays had comparatively failed. In lupus vulgaris the indurated lupus patch was thinned, and a good scar resulted, but the number of sittings was greater. The best results occurred in lupus erythematosus. The danger of promoting the spread of invasion was small. A case of epithelioma, arising from a pigmented naevus near the eye, had been successfully treated by zinc ions, after failure with x rays; in this case the proximity of the eye favoured ionization rather than x rays. Dr. LANGMEAD read a paper on *Infant feeding by undiluted citrated milk*. He said it was generally recognized that infants could not digest unmodified cow's milk. Hitherto all their attention had been centred on the excess of casein in cow's milk, which had been made responsible for the formation of the tough curd. The other important factor of coagulation—namely, the calcium salts, which were also in excess in cow's milk—was ignored. Sir A. Wright had shown that a flocculent curd could be produced if the excess of calcium salts were thrown down by the addition of 2 grains of sodium citrate to the ounce of milk. This method of feeding obviated the necessity of dilution, and consequently of adding more cream and sugar. Whole milk possessed certain advantages over diluted milk, for it was less bulky, and so less likely to produce distension of the stomach, and no cream need be added. The method, moreover, was simple, and little manipulation was required. He had used undiluted citrated milk for three years for his out-patients at the Paddington Green Children's Hospital. About seventy infants, who were not progressing on other methods of feeding, had been so treated, and of each of these a chart had been kept, recording the weights. The milk was always brought to the boil, and 2 grains of citrate of soda were added to each ounce. The results had been entirely satisfactory. All the infants who had continued to attend had gained steadily in weight, and no evidence of rickets or other untoward symptoms had occurred. He considered this method of feeding the best which they possessed. It could not, of course, be regarded as a treatment of acute disease, like acute epidemic diarrhoea. The weight charts of some of the infants so treated were shown. The paper was discussed by Sir A. WRIGHT, Dr. DAVIS, Dr. MILLER, Dr. PAYNE, Dr. WILCOX, Dr. FINE, Dr. TURTLE, and Mr. LAMING EVANS.

THE following are the numbers of medical students in the various universities and faculties of France, as given in official statistics which bring the figures up to January 15th of the present year: Paris, 3,740; Marseilles, 347; Besançon, 31; Bordeaux, 825; Caen, 57; Clermont-Ferrand, 57; Dijon, 105; Grenoble, 82; Lille, 341; Lyons, 923; Montpellier, 586; Nancy, 353; Poitiers, 53; Rennes, 199; Toulouse, 452. The total number is 7,220.

Reviews.

THE PSYCHIC ELEMENT IN DISEASE.

If it be true, as many writers have asserted, that the English as a race are becoming more prone to nervous irritability than heretofore, the fuller investigation and study of such subjects as neurasthenia and neurosis are not only interesting but necessary. Hence, a review of the subject as seen through the eyes of a French physician¹ is worthy of note, more especially when the methods of treatment which he advocates are diametrically opposed in some respects to those which have been generally accepted at home.

Dr. P.-L. LÉVY's book is written as a complement to a previous work on the rational education of the will, and is intended to show how such education may be applied for the relief and cure of the neurasthenic and the neurotic. The original work was published some ten years ago, and the present volume contains many papers that have already seen the light in French medical periodicals. The work, which is divided into two parts, deals first with the theories advanced by the writer and with the lines of treatment founded upon them, accounts of a few clinical cases in which his methods have been proved to be successful being given. The keynote of his teaching is the complete re-education of the will of the patient without the aid of isolation or restraint. He claims that good results can be as well obtained without these aids as with them, and that the period of treatment both for patient and doctor is less irksome. The symptoms induced by indefinite disorder of the nervous system must of necessity be vague; but one of them, at least, admits of more precise analysis, namely, pain. It is always a difficult matter to assess the value of pain as a guide to diagnosis, and to determine the extent to which it may be due to actual physical change. Even where a gross physical lesion may be evident there must always be a nervous element which may be modified, if not altogether removed, by judicious treatment. The methods advocated by Dr. Lévy amount, in fact, to suggestion by the physician after the patient's confidence has been obtained and his will power to some extent subordinated to that of his mentor. Such conditions as sciatica, where exaggerated pain is felt in association with a definite pathological lesion, admit of relief more quickly by suggestion and graduated exercise than by continued rest and palliatives. Rest is not always needed for the relief of the morbid condition, but is induced by the fear of pain, and if this can be removed by suggestion the resumption of ordinary movements conduces to the restoration of health.

In dealing with hysteria, the author does not advocate the use of hypnosis, as the results of compelling the will of the patient are not so good as those obtained by gentler means, smoothing over mental difficulties and gradually re-educating the mind. The actual methods adopted are not unfamiliar. The attention of the patient has to be secured, sometimes by mystic manipulation, and suggestion made with due confidence on the part of the operator. Such proceedings demand a considerable expenditure of time and patience on both sides, and it is obvious that they must be applied by a physician with full belief in his own powers and with plenty of time in which to exercise them. For the family doctor, to whom such cases of neurosis and neurasthenia usually come in the first instance, it would be an impossibility, but it is of vast importance that he should be able to recognize at the outset the relative part played by the psychic element. Cases of pseudo-appendicitis and pseudo-malignant disease are for ever on the increase, and it is possible that a better knowledge of the psychic treatment would lessen the number of instances in which the appendix is found by the surgeon to be itself free from disease.

The latter part of Dr. Lévy's book is mainly occupied in combating the prevalent views as to rest and isolation from relatives and home surroundings. He would treat his cases without interfering with their ordinary round of life, although forbidding access to obvious exciting causes, but he does not appear to recognize that the home surroundings themselves are often the main cause of the

neurosis. The study of the psychic element in disease becomes more useful as life becomes more hurried and exciting, and the work before us should serve to stimulate study in that direction, whether the author's views be accepted or not.

FEEBLE-MINDEDNESS AND ITS CAUSATION.

In a well-got-up volume, *Mental Deficiency (Amentia)*,² dedicated "to all those persons of sound mind who are interested in the welfare of their less fortunate fellow-creatures," Dr. TREDGOLD has set forth an interesting account of the incidence, causation, pathology, mental and physical characteristics, social relationship, diagnosis, prognosis, and treatment of persons suffering from mental deficiency (amentia). The author, in his capacity of Research Scholar in Insanity and Neuropathology of the London County Council, as well as that of one of the medical investigators appointed by the Royal Commission to make inquiry in regard to the number of mentally-defective persons in certain districts (Dr. Tredgold's being Somerset), has had exceptional opportunities of studying the subjects of which his book treats practically, and much that appears in it is based upon original observations, which, however, he very fully compares with the experience of other workers in this field. For some of the statistical tables and illustrations he owes his indebtedness to such authorities as Dr. Caldecott of Earlswood and Dr. John Thomson of Edinburgh. An original drawing of types of brain cells occurring in amentia forms an appropriate frontispiece.

Limiting the connotation of "mental deficiency" to cases in which the mind has never attained normal development, the tables of the Royal Commission are quoted to show that its prevalence in sixteen selected districts of the United Kingdom ranges from a minimum of 1.1 in Cork to a maximum of 4.68 in Lincolnshire. By a series of calculations the author infers that in every 10,000 of the population of England and Wales there are (in whole numbers) 2 idiots, 7 imbeciles, 15 adults and 14 children designated feeble-minded, and 36 insane persons, such a prevalence showing that causation is a subject calling for the gravest consideration.

Dr. Tredgold prefers to classify etiological factors into: "(a) Intrinsic-Heridity," and "(b) Extrinsic-Environment," rather than to call them Congenital and Acquired. To nervous heredity he assigns the first place, finding evidence of it in 80 per cent. of over 200 cases he was able thoroughly to investigate. A pronounced history of family alcoholism he found in no less than 46.5 per cent., but he remarks that in five-sixths of these definite neuropathic heredity was present in addition. Tuberculosis, he considers, is rarely the direct and sole cause of amentia, though it often has "a very important indirect and contributory influence." To inherited syphilis he assigns comparatively small importance as regards mental defect, and to consanguinity of parents no more than is implied in accentuation of common morbid heredities. The importance of abnormalities of labour as a cause of amentia he considers to have been much over-rated. Some graphic charts of family histories serve to illustrate the relative influence of combined factors. As regards pathology, Dr. Tredgold states his conviction that "the essential basis of amentia is an imperfect or arrested development of the cerebral neurones," relegating gross anomalies and diseased conditions of the brain to a secondary place. Some useful tables of the clinical varieties of primary and secondary amentia in relation to their etiology and pathology, and of the anomalies associated with amentia, lead to a consideration of its physical, nervous, and mental characteristics, which are very systematically worked out.

Chapters follow treating of feeble-mindedness in children and in adults respectively, the definitions laid down and the statistics gathered by the Royal Commission being cited in this connexion. "Idiots Savants" are considered in a separate chapter, which is embellished with photographs of the handiwork of the "Genius of Earlswood Asylum." After a discussion of the social relations of

Eng., Consulting Physician to the National Association for Feeble-minded, and to the Littleton Home for Defective Children. London: Baillière, Tindall and Cox. 1908. (Demy 8vo, pp. 321 + xviii, plates xxix, figures 67. 10s. 6d. net.)

aments, methods of treatment and training are dealt with; and in the concluding chapter the problems of after-care, permanent segregation, and the prevention of propagation of the unit are studied in the light not only of prudence but of practicability.

From the account we have given of the contents of the book, it will be seen that Dr. Tredgold has made a very comprehensive survey of his subject, more especially from the scientific and social sides. We are glad to have the valuable research work of the author gathered together into a convenient volume which is easy of reference, and which will be found most helpful to those wishing to gain an insight into the complicated problems of mental defect.

RADIUM AND RADIO-ACTIVITY.

MR. FREDERICK SODDY, Lecturer in Physical Chemistry and Radio-activity in the University of Glasgow, has published very opportunely, so far at least as the medical profession is concerned, a volume entitled, *The Interpretation of Radium*,³ consisting of the substance of six popular experimental lectures delivered at the University of Glasgow last year. Mr. Soddy begins at the beginning, and pursues at first the historical method, giving an account of the observations of Becquerel, Roentgen, and Madame Curie; he then discusses fully, with descriptions of illustrative experiments, the rays emitted from radium, their relative penetrating power, and their behaviour in the magnetic field. He explains the practical effect from the radio-active point of view of spreading a minute quantity of a radium salt over a large area, showing that for practical purposes a thin film of a pure radium salt can be used to give alpha rays essentially free from beta and gamma rays, since the beta and gamma rays from so small a quantity are so feeble as to be practically negligible.

After describing in a general way the characters of the three classes of rays, he discusses at some length the nature of the alpha rays, and gives the grounds for the opinion that they are flights of swarms of helium atoms expelled from the radio-active substance at the almost inconceivable speed of 8,000 to 12,000 miles per second. He describes briefly the experiments by which it was shown in 1903 by Sir William Ramsay and himself that helium was a product of the radio-active change in radium, and gives a fuller account of his own recent research for the purpose of detecting the production of helium from the primary radio-elements—uranium and thorium. Finally he sums up the position as follows:

"Helium has actually been found to be produced from the various radio-active substances—radium, thorium, uranium, actinium—which have in common the fact that they all expel alpha-particles. The mass of these particles has been measured and found to agree with the mass of the helium atom. All alpha-particles have been proved to have the same mass and to differ only in the initial velocity of expulsion, whether expelled from radium itself, from the emanation, from actinium, uranium, thorium, or any other of the bodies which expel them. Hence we are justified in concluding that the alpha-particle is an atom of helium, or at least becomes one after the velocity with which it is expelled is lost and it is brought to comparative rest."

He therefore considers that it is justifiable to write the first disintegration suffered by radium somewhat as follows:

And adds:

"There is a great deal of evidence going to prove that one atom of a radio-active body expels but one alpha-particle at each disintegration. Hence, since the atomic weight of radium is 226, and that of helium 4, the atomic weight of the emanation is presumably 222."

At this point Mr. Soddy harks back to uranium, the probable ancestor, but not the immediate parent of radium, and then traces the history of the "emanation." Radium

possesses the power of endowing objects with radio-activity, but this endowment of alpha, beta, and gamma rays quickly disappears. It is due to an invisible film or deposit on the surface of the object rendered radio-active, for, by sand-papery, the activity can be rubbed off, and then is found on the sand-paper. This "active deposit" is the product of the disintegration of the emanation. The atom of radium expels one alpha-particle (helium), and changes into the emanation, which is a gas, and the emanation expels a second alpha-particle (helium), and changes into a solid, or at least non-gaseous, form of matter. Then the active deposit itself passes through three changes with great rapidity, the bodies produced being known as radium A, radium B, and radium C. Radium B probably gives off beta rays; radium C, the final product of this stage, expels alpha, beta, and gamma particles. The beta and gamma rays or particles, therefore, do not come from radium itself directly, but from radium C, the end product of the change in the "active deposit."

Ra	Em	Ra A	Ra B — Ra C	Ra D
226	222	218	214	210
"Active deposit" rapidly changing.				
2,500 yrs.	5.3 days.	4.3 min.	38 min.	30.5 min.

Radium C after it has given off the rays becomes radium D, a comparatively stable body, which takes probably about seventeen years to change into radium E. Radium E, changes into radium E₂, and radium E₂ gives off beta and gamma rays and changes into radium F, the polonium of Madame Curie, an element which gives off alpha rays yielding another body, radium G, which is probably lead.

Ra D — Ra E ₁ — Ra E ₂	(β γ α)	Ra F	Ra G
210	210	210	206
17 years	9.5 days	7 days	203 days

We have endeavoured to give a general idea of Mr. Soddy's book in the hope that it may induce many to read it, because it affords by an orderly progression from the simple to the complex, and with as little mathematics as possible, a clear idea of the nature of the activity of radium, and the relation of that astonishing element to others which precede and succeed it in the process of disintegration or evolution—it is hard to know which term to use.

OSLER AND McCRAE'S SYSTEM OF MEDICINE.

THE fifth volume of Professor OSLER's *System of Medicine* deals with *Diseases of the Alimentary Tract*, and opens with a discussion on the diseases of the digestive apparatus by Dr. Charles G. Stockton.⁴ The chapter is thoughtfully written, but deals with a variety of questions which arise, and are more fully discussed under their special headings.

The second chapter, on diseases of the mouth and salivary glands, is by Dr. David Riesman. It is illustrated by several coloured plates, and, amongst other things, makes an attempt to deal with the changes of the tongue in disease, but this really important question is dismissed in a few lines. The peculiar tongue met with sometimes in persons who have been rickety in youth, described as like a map of France in departments, is not mentioned, nor is the exfoliating tongue seen in certain cases of hyperchlorhydria. Dr. John McCrae contributes a short chapter on diseases of the oesophagus, illustrated by three good photographs of pathological specimens.

The chapter on functional diseases of the stomach is by Dr. Julius Friedenwald, and in this group are included no fewer than twenty-four headings, which are dealt with in seventy pages, and consequently in a somewhat summary manner. As the phenomena presented by these neuroses are so multifiform it is difficult to give any description that

³ *The Interpretation of Radium*. By F. Soddy, M.A. The Progressive Science Series. London: J. Murray, 1909. (Demy 8vo, pp. 271. 6s. net.)

⁴ Oxford Medical Publications. *A System of Medicine by Eminent Authorities in Great Britain, the United States, and the Continent*. Edited by William Osler, M.D., F.R.S. Assisted by Thomas McCrae, M.D., F.R.C.P. Lond. Vol. V. *Diseases of the Alimentary Tract*. London: H. Frowde, and Hodder and Stoughton, 1909. (Roy. 8vo, pp. 903. 30s.)

will satisfy everybody, but we should have thought there was no doubt about the existence of a form of gastralgia occurring in anæmic women where the pain follows the taking of food, and the symptoms are not unlike those of gastric ulcer, and one in which the pain comes on from fatigue during fasting, and is relieved by a dose of alcohol or by a good meal and rest. Einhorn's division into cases of gastric, central, neurotic, constitutional, and reflex origin, seems to be of comparatively little value, as it includes conditions such as "gastralgia due to cancer of the stomach" and "the gastric pains of cerebral tumour and myelitis." Flatulence might have been discussed under the heading pneumatosis, but only excessive cases of "flatulent distension, with dyspnoea, collapse, rapid and irregular pulse, and cyanosis," seem to be thought worthy of description; whereas no symptom is more common in all conditions of stomach derangement, and none better deserves careful analysis of its causes, such as its relation to defective teeth or the bolting of food. Akoria is, in our experience, more often related to gout than to neurasthenia or hysteria.

The chapter on organic disease of the stomach is by Dr. Charles F. Martin. In the discussion of the etiology of gastric ulcer Dr. Katzenstein's experiments might have been referred to, but it is possible the chapter was written before his paper was published. In the treatment of gastric ulcer Dr. Martin is on the side of those who give little food; he thinks that starvation is "good and often well borne," and that enemata of normal saline solution may replace food for "days or even weeks"; he is at least twice as long as necessary before allowing the patient to resume solid food, provided that all the previous stages have been passed through without pain or other untoward symptom. He is disposed to regard gastro-enterostomy as the ultimate remedy for ulcer of the stomach, while practitioners in this country, in spite of statistics, believe that a large proportion of cases get well under medical treatment. The early diagnosis of cancer of the stomach is the most interesting and important question in connexion with it, and there is much need of a critical discussion of all the various means that have been advocated of recent years to help in diagnosis, but we note as omissions any reference to the value of absence of rennin or to the test suggested by Graefe and Roehmer of the hæmolytic present in the contents of carcinomatous stomachs. Speaking generally, the dietetic treatment is more that of Germany than of England. It is somewhat disappointing, in connexion with stomach dilatation, to find the writer speaking of the stomach as containing an "abnormally large quantity of food" after a test meal. Where dilated stomach with retention of contents is suspected, he presumably examines the stomach from six to eight hours after a test meal, when normally he should find it empty, and to speak of an "abnormally large quantity" suggests that normally there is a small quantity present, whereas there should be nothing but traces of mucus and a few epithelial cells. The importance of these small quantities as a means of diagnosing pyloric obstruction and of indicating the need for surgical interference can hardly be over-estimated, and we should have liked to have seen this more clearly stated.

The chapter on diseases of the intestines is contributed by Dr. Alfred Stengel. Considering the importance of feeding by the bowel, absorption in the large intestine was worthy of discussion, but is dismissed in seven lines. There is some confusion in the mode in which phantom tumour is described; there are, of course, two kinds, and both are mentioned, but as if they might coexist or were much the same thing, whereas they are essentially distinct. Confused ideas on this subject are frequently met with amongst students, for while nearly all know of the general distension of the abdomen described by gynaecologists as phantom tumour or pseudocystitis, they know nothing about the form described by Murchison due to contraction of the straight muscles of the abdomen. In the discussion of constipation, no reference is made to the distinction drawn by some authors between atonic and spastic constipation. The indications for surgical treatment in appendicitis are more conservative than might have been expected from what we know of American practice, but no definite rules are laid down to guide the practitioner.

The chapter on diseases of the peritoneum is by Dr. H. D. Rolleston, and contains an excellent account of all that should be included under this heading.

Dr. Thomas K. Brown has written the chapter on the various ptoses. He does not describe the narrow thorax and small costal angle, the *habitus enteroptoticus*, which has been so generally accepted in Germany as an important element in the production of these conditions. He repudiates the view that any general symptoms are dependent upon nephroptosis, and does not speak favourably of the results of surgical treatment.

Dr. Eugene Opie, who writes on diseases of the pancreas, does not, we notice, give any results of personal observations with Cammidge's reaction. He appears to over-estimate the importance of the state of the islands of Langerhans in diabetes, since Dale has shown that they are not permanent structures, but vary in number with the state of the digestion.

The liver and its diseases are described by Dr. O. A. J. Kelly. He accepts the view that jaundice is always obstructive, but says nothing about those cases in which, while there is a yellow discoloration of the skin and conjunctivæ, no bilirubin appears in the urine, the so-called "acholuric jaundice," while he repeats the old mistake of saying that the absence of bile causes constipation. We note that he believes with Dr. Hale White that ascites in cirrhosis of the liver is a terminal symptom, and that where the patient has survived to allow of repeated tapplings the ascites is due to chronic peritonitis.

It may be said generally that the several articles in this volume are well written and include most of what should be known at the present time upon the various subjects with which they deal. The main defect, inseparable apparently from modern textbooks, is the want of clear guidance on disputed points. A more dogmatic presentation of such questions would be more instructive, or, at least, more impressive, to the minds of students than this judicial balancing of views, which leaves them indisposed to trouble their memory with doctrines about which there seems to be so much doubt.

PUNCTURE FLUIDS.

AFTER introductory chapters on chemical and physico-chemical methods of analysis, Dr. GRUNER, in his *Studies in Puncture-Fluids*,⁵ discusses the characters of the various effusions encountered in clinical work. One of the points to which he calls attention is the differentiation of fluids presenting a turbulent, opalescent, or milky appearance. Where the turbidity is due to chyle, the discovery of fat globules under the microscope, or the fact that ether will render the fluid clear, makes the diagnosis easy. But in what the author terms "pseudo-chylous" ascites, the turbidity may be due to a variety of causes. Occasionally it is to be accounted for by the presence of enormous numbers of bacteria, even in non-septic effusions; the use of a Chamberland filter will then procure a clear filtrate. Sometimes the turbidity may be due to a molecular alteration of the globulins present, possibly associated with a combination of globulin and a fat, forming a lecitho-globulid. Excess of mucin, again, may give rise to a milky or opalescent appearance, especially if the electrolyte conditions do not allow of its complete solution. Sometimes it is found that after a first tapping has brought out a clear, translucent, typically straw-coloured fluid, a subsequent tapping reveals a decidedly milky fluid. The author investigated a case of this sort in which the only change found *post mortem* was extreme cloudy swelling of the convoluted tubules of the kidneys. As neither chyle, bacteria, nor lecithin were present to account for this phenomenon, he suggests that the change was due to an alteration in the physical properties of the colloids, explicable in the light of modern knowledge regarding the chemistry of proteids. "If a change in the electrical charge takes place by which the attraction between colloidal particles and ions is altered, then the former may form aggregates of a size sufficiently different from those in the first tapping to make the fluid turbid." At the end of the volume Dr. Gruner provides an interesting collection of cases in which his chemical and physical examinations of

⁵ *Studies in Puncture-Fluids. A Contribution to Clinical Pathology.* By O. C. Gruner, M.P. London: H. K. Lewis, 1908. (Demy 8vo, pp. 289; 111. 1s. 6d.)

pleural and peritoneal fluids are discussed in relation to the clinical and *post-mortem* findings. The chemistry of pathological effusions is very difficult and complicated, and, as Dr. Gruner remarks, the number of variable factors at work is so great that it is often impossible to establish a positive and certain diagnosis as to the nature and origin of the particular fluid investigated. But though his methods and his results may not always be of immediate clinical utility, they possess a high scientific interest, and we hope that his researches on this important subject will be continued.

PATHOLOGICAL HANDBOOKS.

THE *Textbook of General Pathology*, by Drs. BEATTE and DICKSON,⁶ is an attractive book, well written and well illustrated. The text bears the impress of original research, and the illustrations, which are new and specially prepared for the work, are a welcome change from the semi-diagrammatic, conventional pictures often handed down from one textbook to another. In so far as the book is intended for the average student, it may, perhaps, be objected that the authors give a little too much prominence to matters which they find important from their own point of view, and rather overlook ordinary examination requirements. We by no means recommend the cramming system, but authors of textbooks are bound to bear in mind the desirability of helping the student to assimilate readily all that he is required to know, and not overburdening him with details which are probably beyond his grasp. Take for example, pp. 20-25, on the composition of protoplasm. It is impossible for the ordinary medical student, with his limited knowledge of organic chemistry, to understand a classification of "proteins" into protomemins, histones, sclero-proteins, conjugated proteins, etc.; nor can he be expected to grasp the meaning of "mono-aminomonocarboxylic acids," "heterocyclic compounds," and the like. And in dealing with such subjects as inflammation and the classification of tumours, it must be remembered that the beginner requires a general outline rather than special emphasis on certain aspects of recent research or scientific controversy. Disputed points about "plasma cells" or Maximow's "polyblasts" are beyond his need; and there are possibly even examiners who might feel their omniscience rudely challenged by such terms as "epilepidomata" or "mesohylomata." The authors "propose to adopt practically in its entirety" what they consider to be "the most complete and scientific classification" of tumours; but unfortunately there are several other quite different classifications which are also considered by their respective inventors to be "the most complete and scientific." Until pathologists have arrived at some consensus of opinion on this question of classification, writers of elementary textbooks do not appear to be justified in inviting the student to adopt any one of these recently advanced theories. The omission of some of these disputed or highly technical points would have left the authors space to deal with other and more important subjects which the student expects to find discussed in a textbook on general pathology. There is no chapter on pyrexia; surely this is a serious omission. "Into the general subject of gout and the chemistry of uric acid metabolism we do not propose to enter." With regard to these and other important questions, which arise directly out of clinical work and are constantly raised in the examination room, we are compelled to point out that the student will find himself better catered for in other textbooks on general pathology. We hope that in a future edition the authors will see their way to giving fuller consideration to the student's point of view. What they have written is good; and, with a relatively small amount of cutting down in some directions and expansion in others, they might greatly increase the utility of their work.

In his book on the outlines of general pathological histology, Dr. JULIUS STEINHAUS⁷ provides a useful course of practical instruction in histological technique and

diagnosis. The methods of fixation, section cutting, and staining are carefully described, and the list of formulae for differential stains is particularly full and useful. The descriptions of the various pathological lesions encountered under the microscope are brief, condensed, and likely to be helpful to the student going through a laboratory course in pathological histology. Dr. Steinhaus attaches special importance to his photomicrographs, and considers that good photographs are of greater educational value to the student than drawings. We admit that his photographs are good, and that many of them are useful, but we consider that many important details of microscopic work need for their portrayal the work of a skilled artist, and cannot be reproduced adequately in the best of photographs. Though photographs are better than the fanciful, diagrammatic, and conventional drawings often handed down from one generation of textbooks to the next, they are less instructive than really good drawings which faithfully reproduce typical lesions as they are actually seen under the microscope.

Professor ORTH'S *Pathologisch-anatomische Diagnostik*,⁸ which has now attained its seventh edition, is of particular interest as representative of the teaching in the Pathological Institute of Berlin. The special feature of the book is that its aim is eminently practical. In the first chapter the technique of making a *post-mortem* examination is explained, and in all the succeeding pages the appearances found in the *post-mortem* room are taken as the starting point, every tissue being described in the sequence observed in making a systematic investigation of the dead body. This is an excellent plan, and might be imitated with advantage by the writers of English textbooks, many of whom give the student no instruction on the art of dissection in the diagnosis of disease. Professor Orth enters fully into the naked-eye appearances of morbid tissues, and also gives a good account of the microscopic details in so far as these are necessary for confirming a diagnosis. His descriptions are concise and clear, and the thoroughness with which he covers the ground is admirable. Students who assimilate Professor Orth's instructions may feel confident that they have nothing more to learn in the art of making an exhaustive and reliable *post-mortem* examination.

THE HISTORY OF SPECIAL HOSPITALS.

THE origin, rise, and development of special hospitals have recently found a historian in Mr. RICHARD KERSHAW, the Secretary of the Central London Throat and Ear Hospital.⁹ The story that he has to tell is of more than common interest, and might well have been extended beyond the narrow limits of seventy-eight pages.

Specialism has sometimes been described as a "modern tendency," but to the student of ancient history it must appear a revival. In the days of Herodotus the treatment of disease in Egypt was almost entirely in the hands of specialists, and, although much of it depended upon faith in the powers of the particular deity, there is abundant evidence in the papyri and in the bodies of mummies that physical remedies and manipulative skill were used by specialists with judgement and success. Mr. Kershaw traces, in an early chapter, the more important epochs in the history of medicine, and illustrates them by some interesting archaeological photographs, some of which have already appeared in the published lectures of Dr. Richard Caton at the Royal Institution and the Royal College of Physicians. One of these will demonstrate the fact that "balcony" treatment was even more fully utilized in some of the ancient Greek temples of health than at the present day.

A chronological record of the growth of special hospitals in the United Kingdom during the nineteenth century shows that, like so many of the general hospitals, they owe their foundation to individual medical enterprise. It cannot be said that philanthropy was in all cases the moving spirit, but there can be no doubt that the multiplication of such institutions has relieved much sickness and promoted the study of disease.

⁶ *A Textbook of General Pathology*. By J. Martin Beattie, M.A., M.D., and W. E. Carnegie Dickson, M.D., B.Sc., F.R.C.P. Edin. London: Tebman, Ltd. 1908. (Demy 8vo, pp. 491; 162 illustrations and 4 coloured plates, 17s. 6d.)

⁷ *Grundriss der allgemeinen pathologischen Histologie*. Von Dr. Julius Steinhaus. Leipzig: Akademische Verlagsgesellschaft. 1909 (Imp. 8vo, pp. 170, with over 150 photomicrographs on 25 plates, M.10.)

⁸ *Pathologisch-anatomische Diagnostik*. Von Dr. Johannes Orth. Siebente, durchgesehene und vermehrte Auflage. Berlin: August Hirschwald. 1909. (Roy. 8vo, pp. 789, 438 illustrations, M.16.)

⁹ *Special Hospitals*. By Richard Kershaw, Secretary of the Central London Throat and Ear Hospital. London: Geo. Pultman and Sons, Ltd. 1909. (Roy. 8vo, pp. 78.)

The London Fever Hospital was the first to be established, followed shortly afterwards by "Moorfields," and from their lead a series of special hospitals was started in each succeeding decade, until at the present time they number 167. In those of London alone there are no less than 3,171 beds. The influence of these centres for special study has been far-reaching. The better knowledge of fevers and their treatment, the more accurate study of dermatology and neurology, the scientific advances in the fields of ophthalmic, aural, and laryngeal surgery, may be cited, amongst other benefits, as directly due to the opportunities afforded by special hospitals. The names of Lawrence, Erasmus Wilson, Spencer Wells, Toynbee, Peacock, Charles West, and Elizabeth Garrett Anderson will always be held in remembrance as pioneers whose labours have paved the way to success for the present and future generations of specialists.

That the educative value of specialism has of late years been increasingly appreciated, is shown by the return, here recorded, of the attendance of students, post-graduate and other, at the chief clinics in London. A quotation from the memorable address delivered by Sir James Paget to the Congress of 1881 sums up the case in favour of specialism in terms as conclusive as they are eloquent.

Mr. Kershaw, true to his instincts as secretary to a special hospital, labours to prove that they can be worked more economically than general hospitals, but he admits that the data for exact comparison are not entirely trustworthy. He advocates the system of small payments by lower middle-class patients, and does not regard the liability to abuse by patients of a higher grade with any apprehension, so long as the services of an almoner endowed with common-sense are available.

The small work, admirably presented by the publisher, is concluded by a tabular statement of all the special hospitals in the United Kingdom, with some interesting statistics as to their value as educational centres.

PUBLIC HEALTH LAW AND BY-LAW.

THE object aimed at by the promoters of the Public Health Acts Amendment Act which came into force on January 1st, 1908, was to enable sanitary authorities outside London to obtain, when they so desired and without the expense of promoting a private bill, various additional powers which had been included in local Acts passed in recent sessions of Parliament. The Act is an adoptive one, and before it can be adopted by any sanitary authority the Local Government Board in England and Wales, or the Chief Secretary to the Lord Lieutenant in Ireland, must be satisfied that the adoption is desirable for the particular district concerned. An admirable explanation of the Act, with a very full commentary on the various sections, has been written by Mr. ARTHUR E. CLERY and Dr. J. McWALTER.¹⁰ The text of the Act is given, each section being followed by appropriate comments, explanations, or references suitable to it. The second half of the work includes a summary of recent decisions of the courts with respect to sanitary matters; this is very clearly and intelligibly written, and in each case precise references are given to the full reports. We believe that up to the present time only very few sanitary authorities either in England and Wales or in Ireland (the Act does not apply to Scotland) have taken steps to adopt any portion of the Act. If those who are responsible for advising such authorities will carefully read this explanatory volume, we feel confident that many of them will see the necessity for urging the adoption of the Act within the area of their districts.

The very handy little *Handbook of Sanitary Law* brought out by Dr. Burnett Ham nearly ten years ago has achieved popularity mainly on account of accuracy and ease of reference, two qualities which have been well maintained in the fifth edition, edited by Dr. R. KNOX BROWN and Dr. JOHN EVANS.¹¹ The sections upon dwellings and buildings and upon housing of the working classes are especially clearly written, and not the least useful chapter is that which deals with definitions, where the

bewildering terms "drain" and "sewer" are defined as lucidly as is at all possible in the present state of judge-made law. The Public Health Acts Amendment Act, 1907, is referred to in the chapter on nuisances, but the provisions of the Act which relate to common lodging-houses and infectious diseases are not given under these headings. The Infectious Disease (Notification) Act, and the Infectious Disease (Prevention) Act are, we believe, the correct titles of these two Acts, and not those used in the *Handbook*. The general arrangement of the book is excellent, and the printing leaves little to be desired. The editors seem a little uncertain whether to spell Mr. Wyther Blyth's name with a final "e" or not, and one of them does not appear to be quite sure whether his own name is R. K. Brown or K. W. Brown. We believe it is the former.

With the aid of a large number of well-executed diagrams, Mr. JENSEN, assisted by an unnamed collaborator, has succeeded in producing a most helpful work upon the by-laws of the London County Council as to drains and sanitary fittings.¹² In this second edition he has included the new by-law which deals with the giving of notices and depositing of plans before carrying out any proposed work made under the Metropolitan Management Acts Amendment (By-laws) Act, 1899. The annotations are clearly expressed, and give in clear language the reasons which have led to the adoption of particular regulations. The diagrams are not confined to illustrations of recognized appliances, but include a large number which are dangerous and therefore not permissible. References are freely made to by-laws in force in other large towns, including Liverpool, Manchester, and Birmingham. The necessity for adopting in the construction of drains some material which will stand the pressure and vibration caused by the modern methods of traction is becoming more and more apparent. The advocacy by Mr. Jensen of cast-iron drains in towns is therefore opportune.¹³ He discusses the matter very fairly, and although upon points of detail there may some ground for disagreement with his views, there can be no doubt that his general conclusions are correct. The initial cost of laying iron pipes would undoubtedly be greater than that of stoneware drains, but in the long run they would probably be more economical.

NOTES ON BOOKS.

THE twelfth volume of the reissue of the *Dictionary of National Biography*,¹⁴ edited by SIDNEY LEE, takes the work from Sir Gruffydd Llwyd, a Welsh hero of 1322, to William Mason, the Irish statistician. Among the longest biographies are those of Mary I, the first queen regnant of England; Mary II, the wife of William III; Mary of Modena, the wife of the father of Mary II; and Mary Queen of Scots. Close by is a short note on William Marwood, whose claim to inclusion is that he was the public executioner from 1871 to his death in 1833. Among the medical names we note Sir James Ranald Martin, who, born in Skye and educated in medicine at St. George's Hospital, spent many years as surgeon in the H.B.L.C.S., and finally enjoyed a large consulting practice in London; Sir Henry Marsh, a distinguished physician of Dublin; Dr. James MacKenzie, of Worcester, who helped Lady Mary Wortley Montagu to make known the uses of inoculation before the discovery of vaccination; and Sir James McGilgor, the chief of the medical staff of Wellington's army in the Peninsula, and afterwards, from 1815 to 1851, Director-General of the Army Medical Department, in which capacity he inaugurated the medical reports and returns from all military stations, which later resulted in the annual army medical report. The thirteenth volume, which made its appearance this month, comes down to John Myles, founder of Welsh Baptist churches, who afterwards (1663) emigrated to New England. Among the longest biographies in this volume are those of Milton, Sir Thomas More, and General Sir John Moore, the centenary of whose death at Corunna has recently been commemorated. But it contains a fair sprinkling of medical names—among others, that John Moore, the father of the General, who

was for a time assistant surgeon to the Coldstream Guards, serving with them at Flushing and Poseda in 1748, but afterwards practised in Glasgow, where he graduated M.D. in 1770. He afterwards travelled with the Duke of Hamilton, visiting Voltaire at Ferney, and Frederick the Great in Berlin. He published an account of his travels, wrote the once famous novel, *Zeluco*, and corresponded with Burns. A greater name is that of Dr. Richard Mead. It is rather a Scottish volume, the Maxwells, the Melvilles, the Millars and Millers, and the Murrays claiming a good deal of space.

We received on March 3rd the volume of the Transactions of the first International Congress on Psychiatry, Neurology, Psychology, and After-care, held at Amsterdam in September, 1907.¹⁵ It is edited by Dr. VAN WAYENBURG, who was Secretary-General of the Congress, and contains the text in the original language of the various papers read in the general meetings and sections.

The thirty third volume of the *Transactions of the American Gynecological Society* covers the proceedings of that body at its annual meeting at Philadelphia in 1908. Altogether some twenty-five papers find place, most of them being of a decidedly practical character. The special feature of the volume as a whole is the number of papers devoted to the question of immediate versus delayed operation in cases of ruptured tubal pregnancy. They were followed by a good discussion. The President dealt in his address with the conduct of general anaesthesia, making charges against the profession which fortunately have little or no application on this side of the water. One would gather from his statement that the anaesthesia specialist has not yet been evolved in America; the selection of intelligent nurses for such work is spoken of as an advance to be fostered.

*The Frontiersman's Pocketbook*¹⁶ has been compiled and edited by ROGER POCCOCK on behalf of the Council of the Legion of Frontiersmen. The Legion of Frontiersmen is a civilian, self-supporting, and self-governing association, officially recognized in the United Kingdom, Canada, Australia, South and East Africa, and Bombay, as a means of securing for the service of the State men of good character, who have been trained in wild countries, at sea, or in war. The council registers such men in view of their individual usefulness to a field force as guides, scouts, craftsmen, and irregular mounted rifles. In each country throughout the British Empire, so far as the authorities permit, units are being raised for home defence, and, where men can be spared, for service in Imperial defence in time of war. The pocketbook consists of five parts: I, the training of frontiersmen; II, means of travel; III, collective training; IV, morale; and V, information as to simple medical and surgical treatment when no doctor can be obtained; finally, the book has an index, which might with advantage be fuller, and some blank pages for notes. The contributors to the first four parts are a numerous band, who, in various capacities, have had experience of frontier life, and have been forced by practical necessity to know how best to act in various emergencies, and how to utilize means which happen to be available when approved appliances are not at hand. The information ranges from cooking to the church service, and from the making of knots to the identification of a man-of-war, with, at the end, a short disquisition on camp manners. Part V is also the work of many hands; it is arranged alphabetically, and the information, illustrated by first-aid diagrams, is given in a highly condensed form. It seems, as far as we have tested it, to be thoroughly sound, but probably in another edition it would be thought well to give the Schäfer method of resuscitating the apparently drowned now adopted by the Metropolitan Police. The book is of a kind of dwarf quarto shape, bound in leather, and is convenient for the pocket.

MEDICINAL AND DIETETIC PREPARATIONS.

A Soluble Compound of Veronal.

ALTHOUGH one of the most recently introduced of the many hypnotics prepared synthetically, veronal (diethylbarbituric acid) has attained to considerable favour, and is very widely employed. In common with other articles of this class, however, it is insoluble in water, and certain limitations are thus imposed on its use. To

meet this objection the soluble sodium derivative of veronal has been prepared by Mr. E. Merck under the name "veronal-sodium." It is a dry, white crystalline powder, soluble, according to our experiments, in about five parts of water at ordinary temperatures; the solution is almost tasteless, strongly alkaline in reaction, and the addition of acid at once produces a precipitate of veronal. Veronal-sodium appears well adapted for the administration of the drug by rectal injection; when given by the mouth the acid contents of the stomach would no doubt cause the precipitation of veronal, which, however, might then be more readily absorbed than if administered in the form of powder. Veronal-sodium is also supplied in tablets of 5 grains and 7½ grains each.

MEDICAL AND SURGICAL APPLIANCES.

Combined Tongue Tractor and Chloroform Tube.

MR. FREDERIC LONGHURST (Anæsthetist to St. George's Hospital and the Grosvenor Hospital for Women) writes: The task of controlling the patient's tongue, thus securing a free airway and at the same time avoiding interference with the surgeon's aseptic precautions, is, in certain operations requiring difficult anaesthetic positions of the head, less easy than it should be. In such an operation as that for goitre, in which the head has to be kept in the straight line and generally extended, the tongue in most cases causes difficulty by falling back against the posterior wall of the pharynx, and the general methods in use for obviating this complication are: (1) Levering the tongue forward with the flat of a tongue forceps, and at the same time administering the chloroform through the tube of a Junker inhaler; (2) getting the tongue forward by pushing the angles of the jaw; (3) tongue traction by means of a ligature. All these methods are clumsy, probably interfere with the operator, and leave no free hand to work the bellows of the Junker. These difficulties are greatly accentuated in patients of bad anaesthetic type, such as the short-necked plethoric, the overhung jaw, the adenoid, etc. With the object of trying to overcome these troubles, Mr. J. H. Montague, of 69, New Bond Street, W., has, at my suggestion, made the Combined Tongue

Tractor and Chloroform Tube, shown in the drawing, which is used with a Junker apparatus. The instrument is as simple as an ordinary tongue spatula, with added angles for its adaptation to the mouth and teeth, and a tube for the chloroform vapour. The inner end lies on the base of the tongue, and what little leverage is required to maintain sufficient

traction on the tongue is easily exerted by the thumb and forefinger on the handle, which will be opposite the patient's forehead. In my experience the tongue tractor appears to obviate the necessity of a gag or mouth prop; but should the latter in any subsequent cases be found useful in keeping the lips apart, it could, of course, be used in conjunction with it, though, for the reason given above, I have refrained from complicating the instrument by any such addition. The part of the tractor which lies against the teeth is covered with rubber. The tractor once in position, the mouth can be covered with sterilized gauze, and no interference with the surgeon's aseptic precautions should be necessary throughout the operation. There are, of course, many operations in which it is difficult to control the tongue without interfering with the operator, such as operations on the face, neck, ear, head, etc., and in all these cases the tractor will, I think, be found useful. I have found the administration of chloroform greatly facilitated by it, not only in the most difficult of these cases, but also in operations on other parts of the body remote from the head. The advantages claimed for the appliance are that: (1) It secures a patent airway in operations when the position militates against one; (2) it obviates the necessity of interfering with the surgeon's aseptic precautions; (3) the position of the head and neck need not be altered during the operation for the purpose of securing the airway; (4) it leaves one hand entirely free or working the bellows.

An Ophthalmic Vade-Mecum.

Dr. EDGAR WHITAKER (Diss) writes: I have designed an instrument to fill the want, so frequently felt by practitioners, of an appliance ready to hand for extracting a foreign body from the cornea, painlessly and quickly. It is made the usual size of a silver pencil (3½ in. long), and, as is seen in the drawing, the flat top serves as a seal, whilst the whole instrument lends itself to general purposes of various utility, without impairing its efficiency, and gives excuse for its constant presence. It consists of a small hollow barrel (A), on the top of which screws the cap (B). This barrel has a cavity which exactly receives a tube of ophthalmic tabloid cocaine. The lower part of the barrel is graded off into a fine, but firm, spatula (D) for the removal of the foreign body, whilst the cover (C) effectually prevents injury to this part of the instrument. Messrs. Burroughs and Wellcome have made it for me extremely well in silver and at a most reasonable price.

Anaesthetic Emergency Case.

Dr. A. DE PRENDREVILLE (Senior Anaesthetist to the London Throat Hospital, etc.) writes: The hypodermic case, shown in the accompanying sketch, has points of interest which, I venture to suggest, are worthy of special attention at the hands of practitioners generally and of anaesthetists in particular. Anyone who has, unfortunately, had occasion to face a sudden crisis during a surgical operation must have keenly felt the need of drugs ready for instant use. The case is fitted with nine "steriles" (sterile capsules), prepared with the utmost care. Each sterile contains a single dose of the required drug. The following selection from a list of some 100 formulæ in vogue is suggested, but may be modified at will to suit individual requirements: Adrenalin, camphor in ether, digitalin, ergotin, strychnine, and scopolamine-morphine. One or two of the special injections may be kept in duplicate. A metal syringe and a glass tube of Schimmel's needles are also contained in the case. It is unnecessary to emphasize the great importance of having clean, unused needles for separate injections. Mr. W. Martindale, 10, New Cavendish Street, W., has elaborated my original idea for me, and has, I think, produced a very useful and valuable outfit for hypodermic medication. All the fittings are of metal, and can, of course, be sterilized by boiling.

*A Lacrymal Cannula.*

Dr. G. F. C. WALLIS (late Bristol Eye Hospital) writes: Messrs. Weiss and Co. have made for me the lacrymal cannula as illustrated. It is bulbous-ended like a Couper's probe, and has the opening laterally, which obviates blunting the smooth olivary end, thus allowing of easy passage from the canaliculus into the lacrymal sac. The tube is of soft metal, and can be shaped to any desired curve.

Comedo Expresser.

Not being quite satisfied with the comedo expressers at present in use, Dr. Pernet has had a larger instrument made by Messrs. Mayer and Meltzer. It is in the shape of

a blunt fenestrated curette, slightly bent at the end, and altogether a little over 4 in. long. In the figure it is shown three-quarter size.

REPORTS ON THE ACTION OF NEW DRUGS.

At the last meeting of the International Association of the Medical Press a discussion took place as to the position of medical men who received fees from manufacturing chemists or chemical firms for investigations of the action of new drugs. A similar discussion had previously taken place in Cologne at the meeting of the German National Association. The chief chemical firms had at that time expressed themselves in sympathy with the association, and as prepared to lend their aid in any reasonable manner.

In the *Deut. med. Woch.* of December 10th, 1908, a "round robin," signed by the following firms, gives the details of the steps which they are taking in this matter:

Aktiengesellschaft für Anilinfabrikation, Berlin.
C. F. Boeringer and Soehne, Mannheim.
Chemische Fabrik auf Aktien, vorm. E. Schering, Berlin.
Chemische Fabrik Gustrow, Gustrow i. M.
Chemische Fabrik von Heyden, Radebeul, near Dresden.
Farbenfabriken, vorm. Fr. Bayer and Co., Elberfeld.
Farbwerke, vorm. Meister Lucius and Brünning and Co., Höchst.
Gehe and Co., Dresden.
Gesellschaft für Chemische Industrie, Basle.
F. Hoffmann-La Roche and Co., Grenzach i. Baden.
Kalle and Co., Biebriche a. Rhein.
Knoll and Co., Ludwigshafen a. Rhein.
E. Merck, Darmstadt.
Pearson and Co., Hamburg.
J. D. Riedel, Berlin.
Schulke and Mayr, Lysofabrik, Hamburg.
Dr. Theinhardt's Nahrungsmittel Gesellschaft, Cannstatt-Stuttgart.
Vereinigte Chinin-fabriken Zimmer and Co., Frankfurt a. M.

The Union of Chemo-Pharmaceutical Industrial Firms, of which those enumerated above are members, state that the union condemns the principle of paying fees for public reports on new drugs by medical men. The firms we have named realize that they must protest energetically against the unwarranted suggestion that they have any pecuniary interest in the publication of these articles. It is, however, to their interest that each pharmacological preparation should be subjected to a thorough and careful investigation by experts of good repute. Such an investigation is absolutely necessary to the advance of medicinal therapeutics. The firms in the list we have quoted do not consider that it is any concern of theirs to express an opinion with regard to the payment of medical men for undertaking these investigations. They are of opinion that no honourable member of the medical profession could be influenced in his judgement of preparations by the reception of a fee, and they add that the question should not be confounded with that of writing favourable notices on drugs for gain.

The condemnation expressed in the first sentence of the last paragraph will be greeted with approval by all who are interested in the matter.

MOTOR CARS FOR MEDICAL MEN.

TRICARS.

P. C. asks for information as to the suitability of tricars for medical use, and especially for the personal experience of any doctor who has used them. Our usual motor correspondent has neither personal experience in their use, nor any printed matter available to send to "P. C." for his information. Speaking generally, tricars have not attained to much popularity, and are not reputed to be very safe, especially in taking corners at any pace.

CAR FOR ROUGH ROADS.

MOTOR, writing from the Orange River Colony, asks if any of our readers have experience of the Holsman car or others of similar construction. These have a high clearance, are built for solid tyres, and have air-cooled engines. Solid tyres would probably be an advantage in the Colony provided that the car is built for them, and has appropriate springs. But, in the absence of actual experience, we doubt the advisability of an air-cooled engine, for it is when struggling with difficulties such as a steep hill with a bad road, or clambering out of a watersplash or a gully, that all engines get overheated and lose power. Since air cooling is largely dependent upon the car travelling rapidly through the air, it is just in such conditions that it would be least efficient.

LITERARY NOTES.

In the *Daily Graphic* of March 8th Mr. Herbert Sieveking gives an interesting account, with illustrations, of Tyburn, where so many unfortunate people, sinners and saints, suffered in the bad old days before Romilly cleansed our Statute Book of the blood which stained nearly every page, and before the growth of religious toleration made theological belief cease to be *un cas pendable*. Admirers of Hogarth will remember the ghastly print which brings the "Rake's Progress" to a close. Mr. Alfred Marks has shown in his book, *Tyburn Tree: its History and Annals*, which is based on exhaustive research, that Tyburn was a place of execution for nearly six hundred years. The first time the death penalty was exacted there was in 1196, the last in 1783. The London County Council has decided to erect a memorial at the junction of Edgware Road, Bayswater Road, and Oxford Street. This will take the form of a triangular stone with a representation of the gallows (which was triangular) in brass. The stone in the roadway will be surrounded by a 6ft. triangle with the inscription in brass letters, "Here stood Tyburn Tree. Removed 1759." The determination of the site of the gallows has been made possible by the discovery by Mr. Sieveking of a map of the parish of St. George, Hanover Square, dated 1725. Mr. Sieveking, who is a son of the late Sir Edward Sieveking, is a member of the medical profession.

Epilepsia is the name of an international quarterly journal devoted, as its title imports, to the publication of researches and observations on epilepsy and allied disorders. It will be published in English, French, and German. The founder of the new journal, which is published by Scholten and Holkema, of Amsterdam, and I. A. Barth, of Leipzig, is Dr. Julius Donath, of Vienna, who is also the editor. The Editorial Secretary is Dr. L. Muskens, of Amsterdam. The first number contains original articles by Professor Raymond and Dr. Sérienx, of Paris; Professor Binswanger, of Jena; Professor Redlich, of Vienna, and Dr. L. Muskens.

Dr. Ralph W. Leftwich writes:

I notice that the authors of the two able articles on exophthalmic goitre in the *JOURNAL* of February 13th use the synonym Graves's disease as is usually done in this country. In Germany it is always termed "Basedow's disease," his description, though five years later, being the more exact. A third claim has been set up in favour of Dr. Parry.

It is pretty clear, however, from the passage I am about to quote that the conjunction of the three symptoms—enlarged thyroid, exophthalmos, and mental soundness—was well known to the ancients. I came across it in Brachet's *Dictionnaire Etymologique*. "Goître du Latin *guttur* (autre forme de *guttur*). *Guttur* signifie proprement *gorge*, mais il a le sens de *goître* dans la latinité de la décadence; car on trouve son dérivé *gutturulosus* employé au sens de *goîtreux* dans Ulpian: 'Si quis natura gutturosus sit, aut oculos eminentes habeat, sanus videtur.' This, I suppose in contradistinction to the mental infirmity of cretins, the term "*sanus*" being evidently inapplicable to the body. Ulpian died A.D. 226.

It is certain that "*gutturulosus*" meant a person with a goitre. But we do not think that the passage quoted by Dr. Leftwich proves that exophthalmic goitre was known to the ancients. The whole text is as follows:

Digest, XXI: 1: 12. Ulpianus libro primo ad edictum aedilium curulum. Qui clauum habet, morbosus est: sed et polyposus. Eum, qui alterum oculum aut alteram maxillam inaequalem habet, si recte ita utatur, sanum videri Pedius scribit: ait enim inaequalitatem maxillarum oculorum brachiorum, si nihil ex ministerio prestando subtrahit, extra redhibitionem esse. Sed et latus vel cruris brevis potest adesse impedimentum: ergo et hic erit redhibendus. Si quis natura gutturosus sit aut oculos eminentes habeat, sanus videtur. Item sciendum esse scaevam non esse morbosum vel vitiosum, praeterquam si inebellitate dextrae validius sinistra utitur: sed hunc non scaevam, sed morbosum esse. Is cui est oleum in sanis sit quiescitum est. Probatus aut non esse morbosus ex alicui odore veluti hircosum, strabonem: hoc enim ex illius oris accidere solet, si tamen ex corporis vitio id accidit. Veluti quod iecur, quod pulmo aut aliud quid similiter dolet, morbosus est.

The technical meaning of *redhibere* is to throw back bad merchandise on the vendor's hands. It appears likely, therefore, that the passage deals with the purchase of slaves, and the reasons which justify the buyer in refusing delivery. Possibly it may refer to fitness for military service, but Ulpian does not give the text of the edict of

the Curule Aediles on which he comments. In any case we think the word "*sanus*" simply means "sound" or fit for service, and has nothing to do with the absence of the mental degeneracy of cretinism.

We have seen many complaints as to the irreligious teaching that is forced on the children in France under the present régime. It is said that history is deliberately falsified in the interest of Republican freedom and fraternity. It appears that in some textbooks, at any rate, scientific medicine and its professors are almost as roughly handled as what are called clerical prejudices. Dr. Good, of La Motte-Saint-Heraye, in a letter addressed to the *Concours Medical*, gives some instructive examples from a textbook on domestic economy written by a Madame Sage for the use of girls in upper primary schools. He says his daughter, aged 15, who is preparing for her certificate examination, had called his attention to the following remarkable statements:

The terms employed by doctors are sometimes strange; these gentlemen love to use peculiar and high-sounding language. They seriously speak of a footbath as a *pediluvium*; of lard as *axungia*, etc. Modern medicine should leave aside these quackish ways, and speak in common language.

Again:

Doctors do all they can to make their prescriptions as difficult to read as possible; a doctor who should write legibly would lose his prestige. Truly these are ways belonging to another age.

How the gifted authoress herself can talk in language understood of the people is shown by her advice to girls from 15 to 16 years of age. They are taught that the "expulsion of waste liquid matters should be made as soon as the desire to do so is felt in order to preserve to the muscles of contraction all their sensibility!" No mention seems to be made of gaseous products, but if the like Republican freedom is to be applied to the expulsion of these, a new edition of the learned work of "M. Ortiunus," mentioned by Rabelais as having been found by Pantagruel in the Library of Saint Victor at Paris, and entitled, *Ars honeste petendi in societate*, will be required. How modern are Madame Sage's notions of medicine are one gathers from statements like the following:

Corns on the feet are cured by the application of house leek.

When one is stung by an insect, it is enough in order to cure away the inflammation to rub the wounded part with the leaf of a leek; if the wounded part becomes inflamed, and swells, one must forthwith apply the actual cautery, either red or at white heat, put a bandage on the limb above the sting . . . and have oneself taken to a pharmacist!

Madame Sage's explanation of the intensification of itching in scabies at night, "surprise by himself," as Count Smolensk would say. The girls are told it is because the acarus takes care of its health by knocking off work during the day! The lady's knowledge of the character of the parasite is perhaps derived from familiarity with the ways of the modern working man and his careful limitation of output. Among other things the victims of Madame Sage's instruction are expected to learn is an *olla podrida* of pathology, in which microbes, ferments, toxins, etc., are mixed like the ingredients in the witches' cauldron in *Macbeth*. In a chapter devoted to preventable diseases cerebro-spinal meningitis finds a place. The way to safeguard yourself against this formidable affection is as easy as lying: "One must wash one's hand after having touched the various eruptions seen on the skin of patients suffering from the disease." The young girls are also taught about plague, cholera, psittacosis, and *puerperal fever*. Well may Dr. Good complain of having to pay for such a book issued by official authority. If Madame Sage's work is to be taken as a type of the textbooks put into the hands of the future mothers of France, one may look forward to a generation which will hold the doctor in the same contempt as it is taught to hold the priest. As in Lavoisier's day, *La République n'a pas besoin de savants*.

Messrs. John Bale, Sons, and Danielsson, Limited, are publishing a translation of the second edition of Bandler and Roepke's work, entitled *Tuberculin in Diagnosis and Treatment*. A coloured plate of the local tests is given, and eighteen charts illustrating the tuberculin reaction and the course of tuberculin treatment.

NOVA ET VETERA.

THE STUDY OF MEDICINE IN THE BRITISH ISLES.

DR. NORMAN MOORE is a many-sided man. In his youth he had the good fortune to come under the influence of Charles Waterton, who fostered in him a love of natural history. Later he attracted the favourable attention of Charles Darwin, whom to know was in itself a liberal education in biological science. He has earned distinction as a pathologist and a physician, and he is now Senior Physician to St. Bartholomew's Hospital, a position which must be peculiarly congenial to him for sentimental as for other reasons, for he has given much attention to antiquarian investigations. His well-deserved reputation in this field marked him as especially fitted to succeed Dr. Payne as FitzPatrick Lecturer to the Royal College of Physicians of London. We had the privilege of publishing two of these lectures at the time of their delivery.¹ Dr. Moore recently issued his FitzPatrick Lectures in a handsomely printed and illustrated volume.² In it is embodied a vast amount of original research among the records of the past, digested into a form easily assimilable by any one who has a taste for such studies.

We have often dwelt on the importance even to the self-styled "practical man" of a knowledge of the history of his art. Such knowledge would, for one thing, save him from rediscovering truths known to Galen, devising instruments and appliances described by Celsus and Paul of Ægina, and inventing operations performed by Hippocrates. But more important than this is the knowledge of the evolution of medical science, which shows how the art of recognizing and treating disease has been perfected, the obstacles that have stood in the way of pioneers, and the manner in which they have been overcome. The history of medicine is indeed an object-lesson in the method of furthering knowledge, indicating at once the misleading tracks to be avoided, and the path to be followed in the search for truth.

Dr. Moore carries the history of the study of medicine in this country onwards from the period where it was left by Dr. Payne, who dealt with medicine in Anglo-Saxon times. He shows us how the Norman influence for a time overshadowed that of the native mediciner. He cites the names of several physicians, both lay and clerical, who flourished in London in the twelfth and thirteenth centuries, and gives a kind of medical register of those practising in the reign of Henry III, collected from the writings of Matthew Paris. He thinks it clear that considerable attainments were required before a man was styled *medicus* or *physicus*. If his study was, as Chaucer said of a somewhat later type, "but little on the Bible," it was almost entirely on medical books compiled from the writings of the ancients, and on commentaries on those books by teachers in the universities. A smattering of medicine seems to have been considered a part of the equipment of a learned man, whatever might be his line of intellectual activity. The clergy not only studied but practised the art of healing. King John was attended on his deathbed by the Abbot of Crokestone, who opened his body after death, not, however, with the object of discovering the nature of his disease, but that the corpse might be more decently carried. Richard Grosseteste, the scholarly Bishop of Lincoln, was famous for his medical lore. Among the contents of the libraries of monasteries and cathedrals there were always books on medicine. The library of St. Augustine's Abbey at Canterbury contained ten of the fifteen writers who formed the library of Chaucer's physician, and the catalogue of Christ Church in the same city includes over two hundred and eighty medical works.

Although hospitals in the Middle Ages were mainly institutions for the shelter of the poor and for the accommodation of pilgrims, provision was also made for the care of the sick. In proof of this we have the testimony of Jacobus de Vitry, who, writing of France in the thirteenth

century, speaks of the many associations of men and women who had withdrawn from the world and lived according to the rule of St. Augustine that they might minister to the poor and to the sick. Dr. Moore points out that the frequent contrast in the statutes of these bodies between *sani* and *infirmi* shows that they cared for the sick as well as for the poor. He says that several ancient records indicate that St. Bartholomew's Hospital in London was arranged on the same plan as the French hospitals. In proof of this he quotes a passage from the Close Rolls of Henry III dated March, 1341, which shows that the hospital was intended for the reception of all sick poor until they got well of their ailments, and pregnant women till they had recovered from the effects of their travail. A passage in the will of Gilbert Chaumpneys, dated 1375, and preserved in St. Paul's Cathedral, seems to indicate that "the hospital of St. Thomas the Martyr in Southwark, which now flourishes in Lambeth under the tutelage of St. Thomas the Apostle," provided shelter for the sick.

Dr. Moore takes the writings of John Mirfeld as illustrating the nature and extent of the studies of a physician of the fourteenth century. Mirfeld was a resident in the priory of St. Bartholomew in Smithfield, which was established in the reign of Henry I by Rahere, the founder of the famous hospital which he placed under the patronage of the same Apostle. Mirfeld learned medicine from a master attached to that hospital, of whose practice he gives several examples; he seems also to have attended medical lectures at Oxford. His chief work is entitled *Breviarium Medicinæ*: a full account of it, with reproductions of pages of the two extant manuscript copies, is given by Dr. Moore. The book was compiled in the monastery of St. Bartholomew, and is divided into fifteen parts—the first dealing with fevers; the second with affections of the whole body; the third with affections of the head, neck, and throat; the fourth with those of the chest; the fifth with those of the abdomen; the sixth with those of the pelvic organs; the seventh with those of the legs; while the eighth is devoted to boils; the ninth to wounds and bruises; the tenth to fractures and dislocations; the eleventh to joints; the twelfth to simple medicines; the thirteenth to compound medicines; the fourteenth to purgatives; and the fifteenth to the care of health.

We cannot follow Dr. Moore through his interesting summary of all these, but we may note one or two points by the way. One is his ingenious explanation of the frequent injunctions that certain prayers should be said in making up and in applying remedies. Mirfeld, he says, wrote in a religious house at a time when clocks were scarce and watches unknown, and the recital of prayers or psalms, in addition to its appropriateness to the place, was useful as a fairly accurate measure of time. In treating of injuries Mirfeld expresses regret that medicine and surgery should have become separated, because a man cannot be a good physician who knows nothing of surgery, while a surgeon ignorant of medicine cannot be a master of his art.

In another work, entitled *Florarium Medicinæ*, Mirfeld anticipates some of the advocates of bedroom exercises at the present day. He recommends prelates to have a rope, knotted at the end, hanging from the ceiling of their study, and to swing and raise themselves on it. Dr. Moore sums up Mirfeld's professional character as follows:

In universal humanity towards the sick, and in the wish to alleviate pain and to consider the feelings of the patient, those essential parts of our profession without which the highest skill can never be attained, he was equal to the physician of to-day. He was imperfectly trained in the art of observation, and was inclined to accept without examination the dicta of great teachers of medicine. . . . (He was) a physician of wide reading, with a mind full of all that was known in his time, a laborious and high-minded man, anxious to do all in his power for his patients and to instruct others how to relieve suffering.

As for Mirfeld's medical knowledge, we are told that in medicine he was capable of recognizing the general condition of fever and of distinguishing clearly a few species of disease in which fever occurs—the plague, for example, and tertian ague. He could distinguish to some extent the manifestations of diseases which we call pleurisy and bronchitis. He knew that dysenteric symptoms were not all due to the same cause. He had names for several distinct skin diseases. He had some knowledge of enlarge

² *The History of the Study of Medicine in the British Isles*. The FitzPatrick Lectures for 1905-6. Delivered before the Royal College of Physicians of London. By Norman Moore, M.D. Oxford: At the Clarendon Press. (Pp. 202.)

ment of the lymphatics. He was as well acquainted with epilepsy as most physicians were up to the days of Trounseau. He had observed hemiplegia clinically. He could recognize gout. He knew something of dislocations and fractures. He understood the value of exercise and of rational diet for the preservation of health, and was certain of the ill effects of intemperance. He mentions "sour milk" among the preservatives against pestilential diseases. He was acquainted with some of the effects of opium, of turpentine, of sulphur, and of some other drugs. He understood the necessity of attention to the details of nursing, and was aware of the importance of remembering the effect of the mind on the body. From this it is evident that John Mirfield may fairly be taken as an example of the best type of English physician of the fourteenth century.

Next we come to Thomas Linacre, the founder and first President of the London College of Physicians, who played a considerable part in reviving a knowledge of Greek, and thus helped to bring about the Renaissance. He was, perhaps, more humanist than physician, but he did valuable service to medicine by translating directly from the original Greek works of Galen and other old writers, whose teaching, in the course of translation from Arabic versions into Latin, had become changed as much as Ménage's *Alfama* in its migrations from *equus*. In this way Linacre, though he did not shake himself free from the shackles of authority, helped others to do so by showing the method of observation practised by Hippocrates and the Greeks of the best periods of Hellenic intellectual development.

The translations of Linacre and John Caius opened the way to the study of medicine by the only method that can lead to the discovery of truth. At the beginning of the seventeenth century men began to turn again to Nature, and to look at her not through the spectacles of antiquity, but with their own eyes. The work of Harvey, Glisson, and others was the outcome of the new method; but Hippocrates and Galen continued to hold the minds of men in bondage till long after their day, and even the ridicule of Molière, one of the greatest reformers of medicine, did not kill the blind faith in the ancients which had stood in the way of medical progress for so many centuries.

As an illustration of the professional training of physicians in the seventeenth century, Dr. Moore gives an account of the education of Edward Browne, eldest son of the author of the *Religio Medici*. Browne was educated at Cambridge, where he had the advantage of being under the eye of Glisson. At Cambridge, and afterwards in London, he witnessed a few dissections of the human subject, and he dissected some animals with his own hand. He prosecuted his studies at Paris, Montpellier, and at Padua, where he worked mainly at anatomy. After travelling through many other countries he returned to London, where he became President of the College of Physicians. Summing up Browne's medical studies, Dr. Moore says:

He could write and speak Latin. After taking his M.B. degree he continued his anatomical studies, and worked practically at zoology, botany, chemistry, and pharmacology, and at medicine, parts of surgery, and morbid anatomy. He learned French and Italian, and could speak a little Greek. He used every opportunity of conversing with learned men, such as Swammerdam the zoologist, Glauber the chemist, and Lambechius the bibliographer. He had read widely. . . . Besides his university examination, which was a kind of disputation, Edward Browne was no doubt examined in this college for admission as a candidate in 1658, after he had been engaged in medical studies for about ten years. He took his M.D. degree at Oxford in 1667, when he had studied nine years, and in his own university in 1670. This degree was probably given on proof of study in the faculty. The studies were less regulated, and the practical work less precise than those of a physician in our time. There were as yet no organized schools of medicine in England, and except in this college there was no thorough examination of candidates.

In regard to clinical observation, Dr. Moore says that Caius was the first in England who described a disease from Nature. In his *Liber de Ephenera Britannica*, the preface of which is dated 1555, he gave an account of the sweating sickness. Harvey made notes of some of his cases, but the first writer in this country whose works bear evidence of close clinical observation was Sir Theodore Turquet de Mayerne, a Swiss who settled in London in 1611, and was appointed first physician to James I.

Mayerne left twenty-three volumes of notes of cases, which are among the Sloane Manuscripts in the British Museum. A selection from his notes was published in 1700 by Dr. Joseph Browne. Among Mayerne's notes is an account of the fatal illness of Henry Prince of Wales, who died in 1612, from which it is easy to gather that the illness which cut short a life full of promise was typhoid fever. "So excellent," says Dr. Moore, "are the notes of Mayerne, that it is fair to say that nothing but the pathology of his time prevented him from being the first recognizer of enteric fever." Mayerne also left an account of the health of James himself, which is not only interesting as a clinical record, but important as a historical document. We learn therefrom that the "Solomon of the age," as he was called by his flatterers, scoffed at medicine as made up of conjectures, and useless because uncertain, and had a mean opinion of doctors. In some points the "wisest fool in Europe," as he was described by his tutor George Buchanan, was, perhaps, more enlightened than his learned leeches. Thus he would never allow himself to be bled; it is possible, however, that this may have been due as much to his well-known horror of cold steel as to any reasoned objection. He disliked purging and for a long time would not allow the administration of an enema. In this he showed a stronger will than Louis XIV., who, as shown by the *Journal de la Santé du Roi*, kept by his physicians Valot, Daquin, and Faquin, was ruthlessly purged, drugged, and bled, throughout his life. James's low opinion of physicians may have been founded, like that of Molière, on the fact that he suffered from many infirmities from which probably he got little relief from medical art. He may, perhaps, have taken a pleasure in teasing his physician as Napoleon did with Corvisart. Mayerne has also left records of the health of Anne of Denmark and Queen Henrietta Maria, who evidently had great confidence in his skill.

Another clinician of note whom we can claim wholly as our own was Francis Glisson, author of the famous treatise on rickets which appeared in 1650. Then came Sydenham, whose name is a household word in medicine, and Morton, the author of *Phthisiologia*. In the eighteenth century the most famous names in English medicine were those of Radcliffe, who, though himself no scholar, showed his appreciation of learning by his munificent benefactions to Oxford; Garth, author of *The Dispensary*; John Arbuthnot, deemed by many the greatest, as he certainly was the most learned, of the wits of Queen Anne; Freind, Hans Sloane, Mead, Floyer, and Heberden, one of Samuel Johnson's physicians, whose *Commentarii de Morborum Historia* is the last important medical treatise published in this country in Latin.

Dr. Moore gives a brief but interesting account of medicine in Ireland and Scotland. He gives sketches, each with its characteristic touch, of Sir Thomas Molyneux, whom he calls the first great physician in Ireland; of Dr. John Stearne, one of the original Fellows of the Irish College of Physicians; and of Dr. Richard Helsham, Regius Professor of Physic in the University of Dublin, a friend of Swift, and a correspondent of Arbuthnot. Dr. Moore gives an account of the hereditary physicians of Ireland and of their manuscript literature, to the study of which he has brought the learning of a physician and the special knowledge of a Celtic scholar. In Scotland there were also hereditary physicians. The systematic teaching of medicine began at the University of Edinburgh in the early part of the eighteenth century, and its introduction was largely due to the efforts of Alexander Monro who had studied under Boerhaave. During the eighteenth century the influence of Boerhaave was dominant in Scotland. His teaching, as expounded by his disciples, laid the fame of the University of Edinburgh as a school of clinical medicine. Thus, while the study of clinical medicine among English physicians had its origin in the new learning of the Renaissance, in Scotland it was primarily imported from Holland.

This necessarily brief summary of Dr. Moore's book will, we hope, induce readers interested in medical history to study it for themselves. Only in that way will they be able to form an adequate conception of the recondite learning which forms its framework, and of the literary skill with which the dry bones of antiquarian lore are made to live in its pages. He has undone the work of

Time, which, as Sir Thomas Browne says, antiquates antiquities and hath an art to make dust of all things. The book is a monument of which not only the author but the college of which he is a prominent member may well be proud.

MALARIA IN ITALY.

THERE appeared recently in the *Times* an interesting letter by Professor Osler in which he justly described what has been effected in Italy towards the mitigation of the scourge of malaria as a lesson in practical hygiene. The Italian Society for the Study of Malaria was founded ten years ago, and the results of its work in that period are summed up in the following paragraphs from its decennial report just issued, which are quoted by Professor Osler:

The society has improved the prophylaxis of malaria, and has introduced into practice the new mechanical measures based on the defence of the habitation and the individual from the bites of mosquitos. This being a relatively expensive procedure, the society has occupied itself chiefly with the improvement of the antiparasitic prophylaxis—the administration of quinine.

For this purpose it has promoted and defended legislation for the gratuitous distribution of quinine to the poor and to all workers in malarial localities.

In order to render possible the prophylaxis and to prolong the treatment, it has prepared the quinine in its most agreeable forms, namely, that of comfits and chocolates, the latter containing a tamale of quinine, which has little taste, and is better tolerated by children.

The results have been that since 1902, when the law on State quinine was promulgated, while the consumption of quinine has been yearly increasing, the mortality from malaria has diminished from about 16,000 to about 4,000 yearly; and in the army, Custom House offices, and in some communes where the new laws have been better applied, the morbidity from malaria has greatly diminished.

By these measures, says Professor Osler, and "by means of the agricultural and agrarian transformation of the land and colonization, rather than by the destruction of mosquitos (a thing impossible to be done by us on a large scale)," Italy may be freed from the scourge. He goes on to give a sketch of the history of discovery in respect to malaria, in which he speaks of the "old suggestion" of Lancisi that the disease is transmitted by the mosquito. Lancisi did, indeed, in his book, *De morbis Paludum effluviis*, published in 1717, ask whether "among the living effluvia of marshes there are not some more minute than others which may find their way into the blood vessels and there multiply injuriously"; and he recommended that the blood drawn from persons suffering from ague should be examined with the microscope and the insects found therein (*si qua sint*) closely scrutinized. But the suggestion is much older than the eighteenth century. Varro, writing in the first century before Christ in his book on agriculture, in speaking of the choice of a building site, says that the neighbourhood of marshes is to be avoided, because there grow therein "certain minute animals, invisible to the eye, which gain access to the body through the mouth and nose." Columella, who lived in the first century after Christ, giving counsel on the same subject, says that marshes breed "animals armed with noxious stings, which fly at us in thickest swarms." Professor Osler goes on to speak of the Panama Canal zone, which he says is an astounding witness to the success of modern sanitary measures against malaria. The monthly reports of Colonel Gorgas give a death-rate (among nearly 50,000 work-people) lower than that of any large city; it has been as low as 12 per 1,000. The final establishment of the truth that malaria is transmitted by mosquitos is a notable triumph of the experimental method.

AT a meeting held at the Cultusministerium in Berlin on February 18th, under the presidency of Cabinet Councillor Dr. von Behr-Pinnow, which was attended by representatives of the district centre and the international bureau for the protection of infancy, it was decided to form a national committee for the care of nurslings. The committee is intended to be a central council for the consideration of the measures adopted independently by individual corporations. A German association for the care of nurslings has been founded and will hold its first general meeting in June of the present year.

Medical News.

A COMMITTEE for the investigation of hospital abuse is now in session in the Central Offices of the Assistance Publique, in Paris.

MR. HENRY PHIPPS, of New York, has given more than £200,000 for the purposes of the psychiatric clinic at Johns Hopkins University, Baltimore.

MR. EDGAR TAUNTON, M.B., F.R.C.S., D.P.H., Deputy Medical Officer of Health of Bethnal Green, has been called to the bar at the Inner Temple.

AN anonymous benefactor has recently given, through Dr. John H. Musser, £40,000 to the University of Pennsylvania for the establishment of a department of medical research.

THE Harveian Lecture of the Harveian Society of London will be delivered by Mr. A. J. Pepper next Thursday. It will deal with thirty years' practical experience and practice.

AT a meeting of the Medical Society of London next Monday evening there will be a discussion on the relation of medical men and coroners. It is to be introduced by Sir Victor Horsley.

THE Royal Mail Steam Packet Company has published an illustrated booklet giving particulars of the Easter pleasure cruises that can be made by its steamers to Spain, Portugal, Gibraltar, Morocco, Canary Islands, and Madeira.

THE epidemic of measles still continues in Birmingham, and twenty-three schools have been closed on account of it. In the week ending March 6th 42 deaths occurred from measles, as compared with 43 in the preceding week. No doubt the cold, snowy weather had a good deal to do with the large number of deaths.

A DINNER of a somewhat remarkable character was given to Dr. John B. Deaver of Philadelphia on February 14th. The peculiarity of the dinner is that it was given by more than 150 doctors who had been successfully operated on for appendicitis. A loving cup was presented to Dr. Deaver on the occasion.

IT is announced that by the beginning of the next school year in September the London Education Committee hopes to have established children's care committees for all elementary schools in London, in order to arrange for their apprenticeship or for finding them good permanent employment where there is a prospect of advance.

ARRANGEMENTS have been made for lectures on tropical subjects to be delivered to nurses at the London School of Tropical Medicine, Royal Albert Dock, E. Any qualified nurse may attend the course, whether she intends proceeding abroad or not. The first course will commence October 15th, 1909, and will be taken by Mr. Cantlie, Dr. Daniels, Dr. Andrew Duncan, Dr. R. T. Leiper, Dr. J. M. H. MacLeod, and Dr. F. M. Sandwith.

THE seventh meeting of the Departmental Committee appointed by the Lord President of the Council to consider the working of the Midwives Act was held at the Privy Council Office on March 17th. The following witnesses attended and gave evidence: Dr. E. W. Hope, Medical Officer of Health, Liverpool; Mr. G. H. Fosbrooke, Medical Officer of Health, Worcestershire; Mr. J. R. Kaye, Medical Officer of Health, West Riding, Yorkshire.

THE sixth National Periodical (French) Congress of Gynaecology and Obstetrics and Paediatrics will be held at Toulouse from September 22nd to 27th, 1910, under the presidency of Professor Kirmisson, who will also preside over the Section of Paediatrics. Professor Hartmann will be president of the Section of Gynaecology, and Professor Rouvier, of Algiers, of that of Obstetrics. The General Secretary of the Congress is Dr. Audoubert, Professor of Clinical Obstetrics at Toulouse.

THE German Congress of Internal Medicine will hold its twenty-sixth annual meeting this year at Wiesbaden from April 19th to the 22nd. Among the communications promised are the following: Dr. Magnus-Levy, the metabolism of mineral material in clinical pathology; Dr. Head, sensibility and the testing of sensibility; the same subject will be dealt with by Professor Schoenborn, of Heidelberg; Dr. E. Müller, of Breslau, antiferment of the

tryptic pancreatic and leucocytic ferment: and Dr. Plömes, of Dresden, on the relation between disturbances and diseases of the circulatory apparatus, with special reference to nervous disorders of the heart.

On January 1st, 1909, the number of medical practitioners in Norway was found to be 1,231, of which number no less than 38 are women. This is probably the largest percentage (3 per cent.) of medical women in any country. As the whole of Norway has only about 2½ million inhabitants, and the two largest towns, Christiania and Bergen respectively, about 230,000 and 70,000 only, it is difficult to see how so many medical women can find a living.

THE school of massage attached to the National Hospital for the Paralyzed and Epileptic, Bloomsbury, has proved so successful that it has now been decided to extend the teaching to male pupils. Hitherto only the male nurses of the institution have been taught, but, commencing with Easter Term, outside men students will be allowed to join the classes. The lectures on theory will continue to be in the hands of Mrs. Hawkins, and Mr. J. Richert has been appointed to give practical demonstrations to the men's class. The qualification for membership of the National Hospital Male Nurses' Association will still be confined to those who have obtained the hospital certificate, and the public can therefore, through the association, obtain nurses who are also masseurs.

THE annual meeting of the General Council of King Edward's Hospital Fund for London took place at Marlborough House on March 10th, the Prince of Wales being in the chair. The proceedings were of a formal character, consisting mainly in the presentation and adoption of the report and accounts for the year 1908. The leading events recorded in the report have all been already noticed in these columns. The total receipts for the year were £345,792 15s., and the total distributed £140,000. It is clear that the financial management of this Fund must be of the most admirable kind, for the total cost of administration up to date has been less than 1½ per cent. on the sums received, while when the capital invested in non-trust stock was valued last July it was found to be worth £100,000 more than the sum originally paid.

In our issue of February 27th, attention was drawn to the section of the Minority Report of the Royal Poor Law Commission which dealt with the infant mortality in Poor Law institutions. It was shown that the mortality among infants born in workhouses was extremely high. In the next issue some statistics of the Charité State Hospital in Berlin were quoted, and it was stated that 2,543 children had been born in that hospital in the year 1906-7. We have since ascertained that the number of infants who died in the Charité Hospital during the year under consideration was 152, and that there were 184 stillbirths. The ages of the infants dying in the Charité cannot be stated, so that the figures are not directly comparable with those for the English workhouses, but they certainly appear to indicate that the Berlin mortality is much lower. We are glad to observe that Mr. Burns stated that the statistics quoted in the Minority Report of the Royal Commission are being carefully examined by the Local Government Board.

THE 136th anniversary dinner of the Medical Society of London was held at the Hôtel Métropole on March 10th, with Mr. C. B. Lockwood, the President, in the chair. Covers were laid for over 150 guests, and the arrangements for the comfort of all concerned were admirably carried out by Mr. Bethell, the Librarian of the Society, under the direction of the Honorary Secretaries, Mr. T. H. Kellock and Dr. Leonard Guthrie. The Chairman, in proposing the toast of "The Medical Society of London," said that, though the society possessed admirable premises in Chandos Street, there was not quite sufficient room for its requirements: but the time was not far off when that defect could be remedied. In addition to its library, the society possessed valuable pictures and property. The financial position was so sound that, if it were necessary at once to liquidate, it could pay all its creditors at least eight times over. The toast of "The Guests and Kindred Societies" was proposed by Mr. J. Langton and replied to by Sir William S. Church and by Sir Alfred Keogh, Director-General A.M.S. Dr. J. K. Fowler submitted the toast of the Chairman, who, in concluding his reply, gave the toast of the Honorary Secretaries. After these gentlemen had replied, the company separated.

Two fasciculi of the *Bulletin de la Société Médicale de l'Île Maurice* which have reached our hands contain an

account of the proceedings of the principal medical society in this French-speaking British dependency during the latter half of the twenty-sixth year of its existence, ending December, 1908. Among the twenty or more papers contained are several of interest, and more particularly two dealing with the method of treating abscesses, originally described by Dr. Phillips, of Bradford, in the *BRITISH MEDICAL JOURNAL* on May 16th, 1908. The author of the longer of the two papers, Dr. F. Rouget, considers this treatment constitutes a great advance in surgery, and suggests that it be known as "tight packing." The second paper is equally favourable to it. Dr. Felix records some cases of persistent hiccup in old people successfully treated by subcutaneous injections of quinine, and suggests that in them malarial infection may betray itself merely by a very slight rise in temperature and gastric troubles accompanied by persistent hiccup. Also contained in the two volumes are some four or five papers dealing with the pathology and treatment of malarial fever accompanied by haemoglobinuria, the so-called blackwater fever.

THE second International Congress on Industrial Accidents will be held at Rome from May 23rd to 27th. The official programme of discussions includes the following subjects: (1) The organization of a medical and surgical service for the treatment and observation of the consequences of industrial accidents. (2) The organization of a medico-legal service to deal with industrial accidents and to establish rules for the guidance of doctors who have to examine such cases. (3) Determination and prognosis of the neurotic element in industrial accidents. Under this head is placed the estimation of working capacity before and after the accident. This includes: (a) Methods of examination for that purpose; (b) the importance of the condition before the accident (pre-disposition, previous illnesses, etc.); (c) anthropological and sociological data (race, age, sex, criminality, etc.); (d) the influence of circumstances connected with the accident (legal process, medical examinations, etc.); the influence of forms of compensation on the development of post-traumatic nervous affections. (6) Statistical data from the medical point of view as to the consequences of the application of the compensation law. (7) Functional adaptation of injured joints. Communications relative to the congress should be addressed to the General Secretary, via Borgognona 38, Rome. Papers, which may be written in Italian, French, German, or English, should be in the hands of the general secretary on or before April 1st. Reports introductory to discussions should not exceed sixteen papers should not exceed eight printed pages in length. In each case they should be accompanied by a summary of not more than thirty lines in length.

ON several occasions during the last few years allusion has been made in these columns to the lack of proper provision in the mortuaries of the metropolis for the preservation of bodies awaiting identification and *post-mortem* examination, and we showed as recently as last January that there was a strong case for the immediate filling of this gap in medico-legal machinery. It is with satisfaction, therefore, that we note that the Corporation of the City of London, whose coroner, Dr. Waldo, has been particularly active in urging this reform, has provided a Rechter apparatus, an appliance which works with formaldehyde gas, and affords, in the opinion of many pathologists, a better means of preserving bodies than a freezing machine. When drawing the attention of the jury to this new provision at an inquest on March 12th, Dr. Waldo mentioned that the net outcome of sundry recommendations on the subject which he had forwarded to the London County Council from juries in the other district of which he is coroner, namely, Southwark, was a letter stating that the Council did not at present see its way to provide any means of preserving bodies. It is a somewhat curious result, for the desire for an appliance to preserve bodies in a condition in which they may be identified or examined is no mere medical or legal fad. The value of refrigerators in connexion with public mortuaries has been recognized by the legislature, for a section intended to secure the provision of such aids to criminal investigation was introduced into the Public Health Act (London) of 1891. The cost of appliances which fulfil the purpose in question is not great, and as compared with their practical value is a mere trifle. It is to be hoped, therefore, that the London County Council will reconsider the question. In these days any important municipal authority which neglects to make at one or more of its mortuaries such a simple provision as a refrigerator or equivalent apparatus is guilty of an anachronism.

British Medical Journal.

SATURDAY, MARCH 20TH, 1909.

RIGHT THINKING.

IN one of Goethe's conversations with Eckermann the importance of right thinking was discussed, and the great poet-naturalist somewhat startled his interlocutor by exclaiming, "The worst of it is, it is 'so hard to think!'" This is the common experience of pious persons who practise what is called "meditation"; they too often find, when they try to fix the mind on a given subject, that there seems to be a disturbing influence within the brain which makes the thought wander from the point proposed as its aim. Few, indeed, are those who, like Socrates, can stand forgetful of outward things, absorbed in the pursuit of a train of thought for many hours. Some men think quickly, while the mind of others works slowly. But it is certain that unless one can, in Newton's phrase, "intend" the whole power of the mind to the solution of a problem, the result will be confusion and error. Nothing has more retarded the progress of medical science than loose thinking. Even in men of wide reputation, we have often been struck by the looseness of thought, the carelessness in detail, and the apparent inability to appreciate the nature of proof displayed in matters of ordinary business. This inaccuracy of mind manifested in a sphere where its effects are plainly visible inevitably suggests some doubt as to the soundness of work for the correct estimation of which special knowledge is required. It must, we think, be confessed that medical research suffers from the lack of a proper discipline in the use of the reasoning power in many of those by whom it is pursued. Hence the readiness to assume what has to be proved, the wrong interpretation of facts, and the misuse of statistics which lead to erroneous generalizations and the erection of hypotheses on foundations too flimsy to support them, or even purely imaginary. The "wish 'to believe'" is sometimes as strong a factor in "scientific" investigation as it is in the field of theology.

The history of medicine is to a large extent a record of doctrines crumbling away at the touch of new truth, and of facts laboriously piled up into formulas and pulled down by later knowledge, like the blocks in a child's toy. Many of the greatest advances in medicine have been due to accident, and a harvest has been reaped from seed which the sower thought worthless, or intended for a different purpose. This is why it is so undesirable that research should be tied down to the search for results of immediate practical usefulness.

The study of medical science is in itself of extreme difficulty for the reasons embodied by Hippocrates in his famous aphorism. The uncertainty and elusiveness of the facts makes mistiness of thought concerning them inevitable. All the more, therefore, should we strive to attain at the correct thinking which is our only sure protection from the *ignes fatui* of fallacy that are everywhere about us luring us into the quagmire of error. In his Address in Medicine delivered at Exeter in 1907, Dr. Hale White dwelt strongly on the

all-importance of accuracy of thought in medicine. More recently, at a meeting of the Medico-Legal Society, Mr. Justice Walton delivered an address entitled "A Plea for Correct Thinking." Naturally the judge dealt with the subject from a somewhat different standpoint than that of the physician, but this makes his deliverance all the more valuable. Among other things he said that not long before, during a discussion upon the subjects to be included in a course of studies, when it was suggested that logic should be one of them, he heard a very eminent person ask why young people should be taught an elaborate process for doing that which every man endowed with the use of reason does for himself without thinking. In regard to this point, Mr. Justice Walton asks if the habit of correct thought is so universal as is implied by such a question, "Are we 'always quite sure that our instructors mean exactly 'what they say, or know exactly what they mean?'" He went on to say that of the work that has been done in the past, and still more of the work that is being done at the present time by the observers of Nature, as it discloses itself to them in the heavens above and the earth below, of their patience, their accuracy, their skill, their insight, he could only speak with the humblest respect and admiration. "It 'is only,'" he significantly added, "if and when the 'student of Nature, of the things, which can be 'observed, ventures beyond the ultimate limits of the 'observation and analysis of facts into inferences as 'to that which cannot be dissected and cannot be 'analysed and cannot be seen, weighed, or felt, that 'the lawyer-like instinct begins to prompt inquiries 'which in certain quarters are not unlikely to be 'resented as pedantic and out of date." He urged that he was to some extent justified in suggesting that the lawyer's experience in the practice of his profession afforded a discipline which might be very valuable in dealing with the larger issues involved in the regulation of human society and in the administration of the affairs of the State. We may add that, in our opinion, such training has a very decided value in making the careful sifting of facts and the weighing of evidence for and against a scientific generalization an automatic part of the intellectual process. The lawyer's special point of view arises from the habit, said Mr. Justice Walton, in the first place, of distinguishing facts from theory, of ascertaining facts exactly, and, by a careful examination of the best evidence, of considering the relation between the facts so ascertained and the theory or general rule.

All this is still more necessary in the search for truth in a sphere where the issues are more complicated, the facts more doubtful, and the evidence more difficult to appreciate than is the case in the matters dealt with in a law court. For this reason we have always opposed any narrowing of the preparatory training which should be required of those who wish to enter the medical profession. We need not put over the portals that give admission to it the intimation placed over the door of his school by the old philosopher, that no one but geometricians should enter. But we should insist less on a knowledge of facts such as was considered essential by Mr. Gradgrind, and more on proof of the possession of the power to reason upon facts. Logic is simply the analysis of the manner in which the mind travels towards right conclusions, as grammar is the analysis of speech; it cannot teach a man to reason, but it may show him how to avoid error, as grammar may save him from solecism. Even the despised scholastics might give men who think of scientific research, as

Dogberry did of reading and writing, that it comes by Nature, some useful hints in regard to clearness of definition of terms, accurate statement of the question and rigour of inference from premisses. All these things are too often unfortunately wanting in medical discussions and essays.

UNEMPLOYMENT.

THE subject of unemployment has been so prominently before the public during the last few years, and has come to assume so largely a political rather than an economic aspect, that the essay on unemployment¹ published recently by Mr. Beveridge is a refreshing return to the cooler atmosphere of facts and figures. One conclusion to be drawn from it is that unemployment has been greatly exaggerated and that it does not necessarily mean bad trade, nor could it under existing conditions be removed by making trade better. Further, most of the remedies which take the form of supplying additional employment of a temporary kind have failed to effect their object, and are not likely to succeed, as they do not touch the causes of the condition they seek to remedy, or even assist the class of men for whose benefit they were designed. The figures furnished by the Board of Trade week by week to show the percentage of unemployment are obtained from the books of a small number of trades unions which are in the habit of paying subsistence money to their members when out of work, and are therefore in a position to supply these statistics, but they represent only a small proportion of trades unions, and a still smaller proportion of the total number of labourers.

Mr. Beveridge thinks that the average of 5 per cent. is too high as an estimate of total unemployment, although the fluctuations of the figures from year to year give some idea of the general state of trade. It is somewhat remarkable that unemployment as shown by the trades unions' figures is present during the years when trade is at its best—that is, there is always a fringe of unemployment which must be attributed to personal causes, the less efficient or less industrious workmen most easily losing their employment. Investigation of the books of the trades unions shows that the same men come on the fund year after year. The most important cause of unemployment is the large amount of casual unorganized labour, which leads to the existence of an unnecessarily large reserve of workmen. Where men are employed from day to day every man thinks he has a chance of a job, and consequently an unduly large number of men apply.

Much benefit resulted from the better organization of labour after the great London dock strike, so that whereas before 1891-2 75 per cent. of the dock labourers were casually employed, the latest figures show that 80 per cent. are on the permanent staff, and only 20 per cent. casual. But in a great many trades, especially where there are numerous small employers, as in the building trade, there is a vast number of casual labourers, probably twice as many as can be regularly employed, who are consequently as a class working half-time, never earn full wages, and are always ready to drop into a state of destitution when trade gets slack or other unfavourable conditions arise. Mr. Beveridge's remedy is the creation of State or Municipal Labour Exchanges, worked with the co-operation of employers, who should be willing

to diminish the total number of men employed in their business as casual labourers. The effect of this would be to give certain men more steady employment, but it would diminish the number of men employed, and for the men thus thrown out work would have to be found elsewhere. It is contended that if the change were made at a time of good trade this would not create a serious difficulty.

It is reassuring to be told that investigation of the books of trades unions does not indicate that recent legislation has led to any reduction of the age to which workmen are able to continue their employment; the superannuation tables, in fact, show that the age of retirement is rising. It is not proved that the unemployed comprise a larger proportion of the unskilled workers than of the skilled, but probably they do, since the latter may sink from their position to that of the unskilled, from loss of character or other causes. There is a legitimate demand for unskilled labour, and, although the number of persons who are now seeking such work may be too large, it is not certain that the number of really efficient so-called unskilled labourers who must possess certain aptitudes to be of use is greatly in excess of the demand. At the same time, efforts should be made to direct boys and girls into channels which will lead up to skilled occupations rather than to those "blind alleys" which lead nowhere, and leave those who have followed them when they reach adult life stranded and compelled to join the army of unskilled workers. We may note here that this has in the past been the case with the army, and that it is a reproach which it is within the power of the military authorities to remove or diminish; but the accession of time-expired men is probably one reason why the tables show that the number of the unskilled rises greatly between the ages of 30 and 40.

While the existence of unemployables must be admitted, their numbers may easily be exaggerated, and Mr. Beveridge's remedy is "to abolish the social conditions which pander to idleness and irresponsibility." With regard to recent legislation in favour of the unemployed, the Act which is generally associated with the name of Mr. Long was designed to assist men temporarily out of work owing to dislocation of trade; its underlying idea was to supply them with a bridge which would carry them over the gulf lying between one period of good trade and another. The experience of the Distress Committees in London and the provinces shows the rarity of such persons among those who apply for help, and the impossibility of limiting assistance as directed by the Act to persons who are not in a chronic condition of destitution. Further, it has been found that relief work is not educational; it does not stimulate the industrial habit, the same men being found year after year applying to the committees for help. The relief works have failed to fulfil the laudable object of restoring those employed on them to the ranks of normal industry. Mr. Beveridge believes that such works are altogether in the wrong direction, and that no alteration in the mode of carrying them on can remove these essential defects; they generally imply, he thinks, something that is degrading to the name of work, and disregard the principles of relief.

In addition to recommending the establishment of proper Labour Exchanges and the decasualization of unskilled labour, Mr. Beveridge points to what is done by trades unions themselves to solve the problem of unemployment within their own organizations as showing that the principle of insurance can be suc-

¹ *Unemployment: A Problem of Industry.* By W. H. Beveridge, Stowell Civil Law Fellow, University College, Oxford. London: Longmans, Green and Co., 1903.

cessfully applied. This is admitted by the Imperial Statistical Bureau in Germany, which has considered the question, but the real difficulty is to determine the test of unemployment which should entitle the men to benefit. The value of the test used by the trades unions depends very much upon the local knowledge of the branches with regard to individuals, and, in the opinion of Mr. Beveridge, the practicability of insurance hinges wholly upon whether Labour Exchanges can be worked so as to embrace the whole of the working population concerned. He gives an interesting account of what has been done in Germany towards the perfecting of the system of Labour Exchanges. Much may be learnt by a study of German experience, as different methods have been followed in different parts of the country, and it is very striking that, whereas when they were started ten years ago, trades unionists were hostile, they are now almost entirely in their favour, and the extent to which they are being used, both by employers and employed, is growing rapidly every year.

The second part of the Minority Report of the Royal Commission on the Poor Laws¹ is mainly devoted to the discussion of the organization of the labour market, and its conclusions, though expressed in more flowery language, are not dissimilar from those at which Mr. Beveridge arrives. Both regard the unorganized state of the labour market as the principal matter to which the attention of reformers should be directed, and both urge the decasualization of labour and the organization of proper Labour Exchanges. In the historical account given in the Minority Report to the efforts of the Poor Law authorities to deal with unemployment the view is taken that in 1834 the Commissioners had their attention chiefly directed to unemployment in agricultural districts, and that their recommendations were directed to cure the evils then existing amongst farm labourers. The measures taken were successful, though to what extent they drove the excess of labour from the country to towns cannot be determined, but when it was attempted to apply the same methods to the unemployed class in the towns their inadequacy was at once apparent. From that time to the present local authorities have been complaining to the Local Government Board of their inability to deal with the numbers of destitute but able-bodied persons applying for relief without violating the Board's rules. Test houses, stone-yards, and the like, and, in a few places, special workhouses for their detention, have been tried without any real success.

One of the main recommendations of the Poor Law Commissioners in 1834, which was that the different types of persons requiring relief should be classified and cared for in separate institutions, has not been generally carried out. The Royal Commissioners are unanimous in recognizing this and in advising that classification is essential. It is comparatively easy to suggest means of dealing with the sick, the infirm, the aged, and the defective; it is more difficult to devise an effectual method of dealing with the unemployed and the unemployable. The Minority Report, as we have already stated, recommends the constitution of a Ministry of Labour, to have charge of labour exchanges, industrial insurance, the maintenance

and training of the inefficient, industrial regulation, emigration, and statistics. It appeals to the success that has attended the institution of the Mercantile Marine Offices for Seamen in support of the proposal of compulsory Labour Exchanges for casual labour. It suggests compulsory registration for men found houseless and requiring public assistance, and that inefficient workmen who are unable from want of training to earn their own living should be afforded residence and maintenance on condition that they submit to the necessary physical and mental training, and that penal colonies with power of detention and discipline should be organized for those who will not work. Public works at the public expense are approved provided they are so arranged as to afford additional employment in times when trade is slack; and it is maintained that, by spreading a programme of work over ten years, and borrowing money if necessary to carry out work during bad times, much might be done to diminish the effect of the fluctuations in trade. Such work, it is advised, should not be done by the "unemployed," but by contractors employing men in the ordinary way, who will do a fair day's work for a fair day's pay, and be dismissed if not efficient.

Most people will approve of the recommendations that all young persons should be compelled to attend trade schools and that the half-timer system should be abolished; and many will agree that all destitute mothers of families should have adequate relief—that is to say, complete support—on the understanding that they do no work except looking after their children. As we have previously pointed out, the differences between the majority and the minority do not justify the publication of separate reports. So much is admittedly desirable and is so urgent to be done upon which majority and minority agree that it is to be hoped these minor divergencies will not stand in the way of necessary reform. The reform should not be made a party question. Mr. Chamberlain, Mr. Walter Long, and Mr. Gerald Balfour have in the past shown their desire to grapple with the great and serious difficulties which have grown up in our great towns, and if Mr. John Burns will introduce a bill to found an adequate system of Labour Exchanges, we trust that its principle will be supported by the leaders of both parties in Parliament.

A MEDICAL TOUR.

MAJOR-GENERAL VESEY DAWSON, C.V.O., arranged a tour for the medical officers of the Second London Division Territorial Force extending over the last week-end. All the medical officers in the Division were invited to attend, and seventeen availed themselves of the opportunity of instruction afforded; twenty-five had signified their intention of being present, but owing to the large amount of illness now prevalent, eight had to withdraw. This difficulty is always apt to arise with medical men, and the administrative medical officer had fixed on this season because in ordinary years it is as good a time as any for a man to leave his practice for a couple of days. Among those actually present there were the administrative medical officer, Colonel Andrew Clark, V.D., as well as representatives of general hospitals, field ambulances, battalions, and the sanitary service, and the instruction was so arranged that each was employed in appropriate duty. The military aspect of the tour was directed by Colonel Maude, C.M.G., the general staff officer, and in order to

¹ Report of the Royal Commission on the Poor Laws and Relief of Distress. To be purchased, either directly or through any bookseller, from Wyman and Sons, London; Oliver and Boyd, Edinburgh; and E. Ponsonby, Dublin. (Cd. 4499.) Price 5s. 6d. The second part of the Minority Report has been published, under the title, *The Public Organization of the Labour Market*, edited with an introduction, by Sidney and Beatrice Webb, by Messrs. Longmans, Green, and Co., in an octavo volume of 350 pages, price 5s.

make the work as instructive as possible from a medical point of view, he had the assistance of Colonel Magill, C.B., staff officer to the A.M.O. On arriving at St. Albans at about 5 o'clock on the afternoon of March 12th, Colonel Maude explained the military situation and the scheme of operations which had previously been circulated. The next morning each medical officer proceeded to the point where he would be required, and, having thoroughly mastered the situation, wrote a report: these reports were handed in, and examined and criticized by the directing staff, and subsequently returned to the officers concerned. The next day the various situations were visited by the entire party and the military and medical conditions discussed on the spot. During the stay at St. Albans lectures were given by members of the directing staff on the medical service in the field in time of war, on the sanitary aspects of the present operations, and on the adaptability of buildings for medical services. Those who took part in the tour were unanimous in expressing their sense of the benefit they had derived and the practical knowledge they had gained; it is only to be regretted that more were not able to take advantage of the opportunity for instruction. At a staff ride of the officers of the Second London Division last November four medical officers were present, and five medical officers intend to take part in another staff ride of the division to be held next week.

INCOMPATIBLES AMONG ANTIBODIES.

The members of the Antivaccination League who attended the annual meeting recently held in London in diminished numbers must have dispersed, perhaps in a wiser, but certainly in a sadder mood. They were prepared for a depressing time by the particulars circulated in the annual report of declining interest and exhausted funds. To arouse the League from the condition of anergic stupor into which it had lapsed one of the most voluble leaders of the movement had prepared a wonderful serum with which he experimented on the assembly. He urged the extension of the objects so as to include "the legal prohibition of vaccination and of the intentional introduction of any diseased product into any living animal, either for prophylactic or curative or experimental or any other purposes." This was the panacea for the evils and troubles which confronted the League; but it did not act successfully. So far from acting as a remedy, the most strenuous opposition was aroused, and most of the speakers strongly protested against the scheme, which was wisely withdrawn. For some years, as we have pointed out in these columns, dissensions among antivaccinators have constituted a leading feature at these annual meetings, and on the recent occasion these were more pronounced than ever before. The *Vaccination Inquirer* for March refers to the "brisk discussion" on the paper, and mildly states that "this year's annual meetings will no doubt have produced somewhat mixed impressions on the minds of those who were present." Reference is also made to the "lull in the movement." A long letter of castigation, addressed to the League from one of the pillars of the cause, appears in the official organ. He regrets the decadent tendencies which he observes in the League, and which he avers, if not stopped, will work its utter downfall. One of these is "the attempt to procure prohibition of vaccination." Of this proposal he writes: "Our Advisory Committee will be appointed to the command of the home fleet long before there looms upon the horizon of practical politics any shadow of a shade of the possibility of the enact-

ment of such a law. . . . The thing is a nightmare: it shall never be realized, save after and against all that one man, at least, may do to stay so base a wrong." This declaration and determined attitude of Mr. Alfred Milnes, whose name is so well known to the antivaccinators, when read at the annual meeting, must have staggered those who heard it; we cannot believe it merely produced somewhat mixed impressions. No less forceful was the opposition hurled at the other "decadent tendency" by which it was proposed to kill two birds with one stone. The scheme to join issue and work hand in hand with antivivisection societies was resented and condemned. Altogether Mr. Swan, who contributed the paper, appears to have had a trouncing which must have made him wonder if by any chance he had wandered into the enemy's camp instead of being among his own friends. More interesting, though more depressing to the League, were certain statements made by Members of Parliament who were present. Mr. R. C. Lehman, M.P., is reported in the *Inquirer* to have been "rather despondent about further legislation just at present." Mr. Arnold Lupton, M.P., "thought it was a drawback to their movement that there were now fewer imprisonments. He felt the most sincere contempt for the new Act. As far as the present House was concerned he thought the best line was the anticom-pulsion line. He had little difficulty in getting many members to agree with him as to that, but when it came to the case of vaccination itself it was another matter." This candid confession of the failure of his efforts in season and out of season is refreshing and supports the contention of the pro-vaccinists that despite the machinations of the antivaccinators no advance has been made in the attack on vaccination *per se*.

BOXING A CHILD'S EARS.

At the Leeds County Court on March 12th an infant claimed through her father £9 6s. for personal injuries sustained through the defendant, a certificated school teacher, having boxed the ears of the child. It appeared, according to the report in the *Times*, that an abscess was caused, and the girl, who gave evidence, was still being treated for deafness. It was elicited that the plaintiff's head struck the back of the seat when her ears were boxed. The doctor who had examined the child attributed the injury to the ear to a blow. The judge referred to a case in which it had been decided that a certificated teacher had a right to do that which a parent had a right to do. He therefore found for the defendant. Taking the report as it stands, we venture to submit, with all respect to the judge's decision, that boxing a child's ears is a stupid way of inflicting punishment: the child is taken un-awares, and is afforded no opportunity of pleading for a mitigation of the punishment, which may be a life-long sentence. Granting that a certificated teacher has a right to do that which a parent has a right to do, then if the law permits a parent wilfully to do what is commonly acknowledged to be detrimental to his child's health the time is ripe for the amendment of the law in the interests of the offspring and of the country. We are glad to be in a position to state that the London County Council does not allow the boxing of the ears of children placed under its care in the elementary schools. We believe that in these schools when corporal punishment is called for under no circumstances is it permitted to strike the head. It is important to note that under this regulation the teacher's power of control has by no means been diminished. On the

contrary, we understand that the number of cases requiring punishment of a corporal nature has enormously diminished in the London County Council schools within recent time. It is probably no exaggeration to estimate the diminution in the number of these cases as 90 per cent. This happy result is explained by the power of inflicting punishment being placed in the hands of all teachers. Every case in which punishment is inflicted has to be recorded in a book. Formerly only the head master or the head mistress of a school was allowed to inflict punishment, with the result that a troublesome child, knowing full well that the teacher dared not hit her, when corrected would put out her tongue and make grimaces; and the teacher, on her part, also knew full well that if she were continuously sending up cases to the head teacher for punishment, the head teacher, not having witnessed the transgression, was apt to come to the conclusion, and to tell the teacher, that if she were not able to control the children without punishment then she was not competent for her post. Under the present system a child, knowing that the teacher can hit her on the hand, has no option but to abstain from making grimaces when corrected. On the part of the teacher who has not the right to inflict punishment it is only fair to state that the conduct of the children under her care must at times be most exasperating, but willfully to box a small child's ears seems to be an admission of a want of control of temper on the part of the teacher.

LONDON SCHOOL OF TROPICAL MEDICINE.

SIR FRANCIS LOVELL, C.M.G., Dean of the London School of Tropical Medicine, is making a tour through some parts of the tropics. As Hannibal went about endeavouring to stir up enemies against Rome, so Sir Francis Lovell, with rare devotion, is giving time which he might well spend in the enjoyment of well-earned rest to the attempt to enlist aid for the campaign against the invisible enemies of one kind or another which are the causes of tropical diseases. We are glad to learn from the *Ceylon Independent* that he has been cordially welcomed by the members of the British Medical Association there. On February 16th a dinner was given in his honour at Colombo. Dr. H. George Thomasz, President of the Branch, was in the chair, and among those present were Sir Allan Perry, P.C.M.O., Dr. Aldo Castellani, Dr. M. Sinnatamby, Professor Browning, and many others. Dr. S. C. Paul, who was in charge of the arrangements, acted as croupier. Dr. Thomasz proposed the health of Sir Francis Lovell, who, in responding, said the London School of Tropical Medicine was now entering on its tenth year of existence. From relatively small beginnings, its work had been gradually expanded, so that at the present time the school had an annual entry of from 90 to 100 students, and a staff of five salaried teachers, whose entire time was devoted to teaching and investigation, and of ten lecturers, each of whom delivered a course of lectures on his special subject three times a year. The large number of post-graduate students (816) who had passed through the school, and the fact that year by year the length of the average attendance of the individual student had steadily increased, indicated that the school met a want. In addition to teaching, the school had endeavoured to prosecute and encourage research in tropical medicine. With this end in view, through the assistance of the Government, special chairs had been established in helminthology, in protozoology, and in anthropology. Moreover, the staff of the school was prepared to continue to give help to workers on tropical subjects who could not take furlough to England. A museum illustrative of

tropical pathology and hygiene was gradually being formed, and one important branch of it was the collection of blood-sucking insects and other animals concerned in the transmission of disease. The collections were being arranged in such a manner that a student, about to proceed to the tropics, could see at a glance and easily study from actual specimens not only the disease germs, but the disease transmitters of the particular colony or protectorate in which he proposed to work. In addition to teaching and investigation carried on in London, the school from time to time had sent Commissioners to various places in the tropics to study special diseases. These expeditions had added materially to knowledge, and it was to be regretted that, from lack of funds, they had not been more numerous. Sir Francis Lovell went on to say that the principal object of his mission was not merely to raise funds for the school, but to bring before the residents in the tropics the advantages which they were likely to derive from the research work which had been done and which was likely to be done by the London School of Tropical Medicine. He was glad to say that since his arrival in Ceylon the Governor had very kindly consented to grant the school an annual subsidy of £100 a year for five years, subject, of course, to the sanction and approval of the Legislative Council and of the Secretary of State. This was the same course which had been followed in the case of the other contributing colonies. In addition to the subsidy from Ceylon he had been able to enlist the sympathies of the members of the Chamber of Commerce: an appeal would be issued on behalf of the school for support, and he had every reason to believe that the appeal would be favourably entertained. In addition to this, the matter had been brought before the Committee of the Planters' Association at Kandy and he had every reason to believe that the members of that association would also give a favourable response.

DISINFECTION BY STEAM.

IN so important a subject as the disinfection of objects in daily use, it is primarily essential that the processes which govern the life and death of pathogenic and non-pathogenic micro-organisms should be minutely studied and understood. When every fact concerning the tenacity of life of micro-organisms is thoroughly mastered, the germs will no longer be a menace to mankind. In the meantime we must content ourselves with discovering the laws which underlie these processes generally and giving practical application to this knowledge. Disinfection can be carried out in many ways, but for practical purposes the methods available are restricted to certain chemical substances, certain biological products, and heat. In practice heat can be applied only under certain restricted conditions. Professor S. Delépine has recently published¹ a very clear account of the conditions governing the use of steam both at low and high pressures. He points out that the following conditions must necessarily influence the resistance offered by the organisms: (1) The presence or absence of spores; (2) the amount of moisture; (3) the nature and amount of associated material, such as blood, etc.; (4) the nature and amount of material intervening between the bacteria and the source of heat; and (5) the temperature. Having disposed of these matters briefly, Professor Delépine describes the essentials of practical steam disinfection. He deals only with disinfectors working with current steam, and leaves it to the reader to adapt what is said to apply to confined steam disinfectors. The time required to heat and fill the disinfecter with dry, saturated steam

¹ *Medical Chronicle*, December, 1908.

varies, of course, with the construction of the disinfector; but he states that an apparatus of usual size would take at least thirty minutes, and that from ten to fifteen minutes should be allowed for the steam free from air to penetrate through 8 to 10 in. of mattress or blanket, so that in practice about three-quarters of an hour, therefore, must elapse before the bacteria at the centre of the material being disinfected are acted upon by the steam. Professor Delépine next considers the actual killing off of the bacteria, and taking as a standard a bacterium of a resistance not exceeding that of the spores of *Bacillus anthracis*, he finds that at ordinary atmospheric pressure, current steam kills within five to fifteen minutes. If it is required to kill the resistant spores of earth bacilli, at least two and a half hours' exposure should be allowed. He gives a table showing the time required for the three stages under certain conditions, and concludes that ordinary disinfection would occupy a period of from three-quarters of an hour to two hours, while sterilization would require from three to over nine hours. With steam under a pressure of 10 lb., that is, at 115° C., the reduction in time is only a few minutes. Under 20 lb. pressure, complete sterilization can be completed in from 45 to 130 minutes. Thin materials can be rapidly dried after exposure to dry steam above 100° C. by removing to a dry shed while still hot; but with steam at 100° C. drying is more difficult. In summing up the advantages of high compared with low pressure disinfectors, Professor Delépine relies chiefly on the time factor and the ease in drying. The cost of the low pressure apparatus is usually, although not necessarily, less than that of the high, and the same may be said of the weight. Low pressure disinfectors are frequently more simple and worked more easily.

THE CLAIMS OF DENTISTRY.

MR. MORTON SMALE, Consulting Surgeon to the Royal Dental Hospital in Leicester Square, made some good points in his address from the chair last week at the annual general meeting of governors. Speaking of the efforts of the staff to spare their patients all superfluous pain, he showed that nitrous oxide has been administered at the institution over half a million times without a single fatality. As for the excellent dental school which is carried on in connexion with this hospital, he indicated that whatever might be the case at hospitals of an ordinary type, dental work on a large scale could not possibly be carried on without the assistance of students. In its indebtedness to the student the Royal Dental Hospital does not really stand alone, for, as we have shown on sundry previous occasions, the presence and co-operation of students must necessarily be of immense importance in medical institutions of every kind. It may be conceded, however, that in any great dental institution students are not merely an advantage, but an essential. Hence the point is one which may fairly be made and wisely emphasized at a time when, under the influence of one or two verbose cranks, there is a certain tendency among the less well-informed section of the public to resent the utilization of hospital wards for teaching purposes. Mr. Smale also stated that at the Royal Dental Hospital 20 per cent. of all fees received from students is made over to the general funds of the institution. Unfortunately, however, these fees are but a drop in the ocean compared with the financial needs of the institution, which is seriously embarrassed by the necessity of early liquidating the heavy expenditure involved by the erection of its present buildings. As some £43,000 still remain to be paid, such a degree of economy has to be exercised in the

working of the institution that full advantage cannot be taken of many of those modern contrivances and arrangements by which efficient work is elsewhere facilitated. In spite of this fact, the work done is as excellent as its volume is great. That its value is amply recognized by the three great Metropolitan Hospital Funds, which make it their business to ascertain the precise merits of every institution seeking their aid, is not enough. It should be equally recognized by the general public, more especially at the present time, when the exceedingly important part which may be played by dentistry, in improving the health of individuals and in conserving the physical efficiency of the nation, has at length been realized.

DEATH BY LIGHTNING.

DR. D. CAMPBELL WATT, of Pietermaritzburg (in a letter published in the *Transvaal Medical Journal* for December, 1908), discusses the conclusions and generalizations advanced in a paper on Death by Lightning Stroke, read by Dr. Spencer, of Middelburg, before the Special Subject Section of the Medical Congress at Pretoria. Dr. Watt is qualified to deal with the subject by considerable practical experience, for electrical storms of terrific violence are common in South Africa, and deaths from lightning are frequent. While acknowledging the value of Dr. Spencer's "able" and "exceedingly suggestive" paper, Dr. Watt combats the view advanced therein to the effect that "lightning only burns the human body" "when it meets in its course some metallic object." Dr. Watt cites a case which he saw, where a horse and rider were struck dead by lightning, and where, "although the man was undoubtedly burnt" and singed, there was a total absence of fusing of any "metallic object worn on his body, and of any" "apparent connexion between the metallic objects" "and the burns." There are other points discussed or referred to in the letter, but we must content ourselves here with giving Dr. Watt's conclusions regarding the injuries and appearances which may be found on the body of a person struck by lightning. He says: "It seems to me that the following propositions may be advanced: (1) Lightning stroke may cause no "external injury to the body struck, or it may cause "extensive injury, both external and internal—" "including fracture of bones and laceration of soft "tissues. (2) Death may follow with no apparent "external injury, as well as often extreme wounding, "and is usually instantaneous. (3) Recovery may "take place, even with injury to the tissues. (4) Death is generally due to shock, or to de- "struction of vital centres. (5) Rending of clothing "has often the appearance produced by an ex- "plosion from within outwards—that is, the ragged "edges are everted as in a wound of exit; and the "clothing may be stripped from the body and hurled "away a distance. (6) These ragged edges may not be "scorched, even although in proximity to parts of "the body scorched. (7) Singeing of the hair and "burning of the skin may occur quite independently "of the fusing of metals or the clothing, or in con- "junction with fusing of metals and burning of "clothing. (8) The stroke may affect the skin and "clothing alternately in a zigzag course down the "body, or the damage to both may be at the same "spots. (9) A wound may be accompanied by burning "and singeing about its lips, or it may not. (10) The "body struck may or may not be hurled to a dis- "tance, and an appreciable interval may elapse before "it falls. (11) A red arborescent streak may be present "on the body, and, if present, is pathognomonic. "It should not be mistaken for tattooing. (12) Rigor "mortis does occur. (13) The blood does coagulate

"after death. (14) A *post-mortem* examination reveals "a contracted left ventricle, and congested lungs and "brain. (15) Symptoms in the living are: Some "degree of coma or confusion of mind, dilated pupils, "headache, feverishness, tingling, paresis, vomiting, "and other symptoms caused by shock, together with "others dependent upon any local injury. (16) The "amount of damage done, or of symptoms produced, "will depend, among other things, upon (a) the "strength of the current coming in contact with the "body; (b) the path of the current through or along "the body; (c) the susceptibility of the individual "struck to shock." The *post-mortem* appearances in a case of lightning stroke may be of great importance from a medico-legal point of view.

SMALL-POX AND THE BRISTOL GUARDIANS.

AN outbreak of small-pox is reported from Bristol. The facts are set forth in a letter to the *Times* of March 15th by Dr. D. S. Davies, medical officer of health, who says that an introduction took place in December which led to fifteen cases of small-pox. The last case was notified on March 1st from the country district outside Bristol. Another introduction took place into a public institution on February 16th; from this case seven persons in the city were infected, all of whom were removed to hospital and are doing well. During the week before the date of this letter only one notification of small-pox was received. A specially-summoned meeting of the guardians was held on March 10th. Dr. Sweeting, one of the medical inspectors of the Local Government Board, attended. He informed the guardians of the facts, which gave rise to anxiety, and suggested that increased facilities should be provided for the encouragement and promotion of vaccination and revaccination. Scant courtesy was accorded to Dr. Sweeting, and his proposals were rejected by a majority of 10. For the increased facilities 16 voted; against, 26 votes were cast. Those who spoke against the proposition appear to have been more concerned about the expense of extra vaccination than about the safety of the community. The proceedings, which lasted nearly three and a half hours, were of a most uproarious character. The rejection of the resolution is said by the local press to have been announced "amidst a scene almost approaching "hilarity." Now that the guardians have refused to put into force the statutory powers in regard to vaccination during epidemics, it is possible that they may be superseded by the Town Council, a course which will reflect little credit on the guardians. The members in the minority spoke sound words of common sense, and notice was given by one of the number to move the rescission of the resolution a fortnight hence. It is comforting in the circumstances to learn from Dr. Davies that, so far as the city and port of Bristol is concerned, there is at present no epidemic; but the special precautions as to vaccination and revaccination advised by the Local Government Board, and being actively adopted, are in order to anticipate any extension in the country districts and reintroductions into the city, and to prevent extension from the cases already introduced into Bristol.

INFECTIOUS DISEASES IN LONDON SCHOOLS.

THE Education Committee reported at the meeting of the London County Council on March 16th that during the period from August 24th to December 19th, 1908, 101 schools were under observation for diphtheria,

526 children were tested bacteriologically, of whom 38 were excluded on account of diphtheria or suspicion thereof; one department and three class-rooms were closed; 505 schools were under observation for scarlet fever, and seven class-rooms were closed; and 492 schools were under observation for measles, and two departments and twenty-four class-rooms were closed. Dr. Beaton, in commenting on the report, expressed his regret that the Committee should dismiss a subject of this importance in a report of five lines. In the course of a year over 50,000 children in the schools of London were infected, and over 1,000 deaths occurred. He asked the Chairman of the Committee whether something more could not be done to lessen this mass of preventable suffering. In 1908 the Medical Section of the Education Committee met twice, once in January and once in December. Surely more vigorous measures could be taken. Dr. Beaton urged that stricter attention should be paid to the cleanliness of the schools, and to thorough disinfection when an epidemic occurred. At present London schools were only washed once in three weeks and swept once a week. As to disinfection, an instance came to his knowledge recently where an epidemic of scarlet fever which had been going on intermittently for three months was entirely stopped when the school premises were thoroughly disinfected. But Dr. Beaton's was a voice crying in the wilderness. The subject interested neither party on the Council. The discussion was not continued, and the report was received.

PENSION FOR MOSQUITO BITES.

PENSIONS are given for wounds or disabilities contracted in military service. At the present day bacilli are more destructive to an army than battles, and recent research has shown that the mosquito disables more men than the rifle. It is, therefore, we think, only fair that a nation should express its gratitude in the same way to men in the employment of the State who face danger and contract illness in the course of experiments for the good of their country and of mankind at large. We are glad, therefore, to learn from the *Boston Medical and Surgical Journal* that John R. Kissenger, who, as a soldier in the army in Cuba, submitted in December, 1900, to the bites of yellow fever mosquitos in order to assist in the promotion of a knowledge of the mode of spread of the disease, and has been an invalid for a number of years, is to be rewarded for his devotion. A bill has been introduced in Congress providing for a pension for his relief.

MEDICAL MEN AND LEGACIES FROM PATIENTS

A COMMUNICATION has been received from Major Rawnsley, R.A.M.C., in which he complains that the paragraph published under this heading in our issue of March 6th, page 621, reflects upon him personally as one of the plaintiffs in the action referred to. We did not for one moment intend by this paragraph to make any reflection whatever upon him, nor do we see how it is capable of being so interpreted. We desire, nevertheless, at once to express our sincere regret that Major Rawnsley should have placed such a construction upon it, and we take the earliest opportunity of saying, unreservedly, that there is in fact no foundation whatever for any reflection being cast upon Major Rawnsley, or, indeed, for any imputation of any kind being made against him in connexion with the action in question.

At the meeting of the Medical Faculty of the University of London to consider the proposal to form a Board of the Faculty, the scheme published in the *JOURNAL* on March 6th, p. 636, was adopted in principle, and the suggested constitution approved, with the addition of the Representative of the University on the General Medical Council. The meeting was adjourned until March 26th, when the remainder of the scheme and the resolution to give effect to it will be considered.

THE PRINCE OF WALES paid a visit of inspection to University College Hospital on March 12th. His Royal Highness was conducted round the wards by Sir Thomas Barlow, Senior Physician to the hospital. The Prince, who, as is well known, has a special knowledge of hospitals, in which he takes a keen interest, expressed his approval of the arrangements at University College Hospital, and the cheerful and airy appearance of its wards. His Royal Highness afterwards visited the new buildings of the medical school, and the new nurses' institute.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Imported Meat.—Last week several questions were asked with reference to diseased meat sent from America. Mr. Godfrey Baring asked about diseased livers recently landed to which the official label of inspection was affixed, and which had been reported on by the medical officer of the Port of London. Mr. Burns said he had seen the report, and was aware of the statements contained in it to the effect stated. This particular case was receiving his attention, but he might state that the action reported by the medical officer of health was taken under the Public Health (Foreign Meat) Regulations, which he issued last year for the purpose of preventing danger to the public health from the importation of diseased meat, and which he had every reason to believe would be found effective for the purpose. In answer to another question, Mr. Burns said that the offal referred to in that report bore an official label indicating that the boxes containing it had been inspected and passed in the United States. The matter was receiving his attention; but he might point out that any label attesting official inspection abroad did not exempt meat of the kind referred to from inspection in this country, and that, under the regulations, if it was found to be diseased it must be either exported or destroyed. Mr. Courthope further asked whether in view of the statement that many cases of cancer had arisen in this country owing to this diseased liver, he would prohibit it in the future. Mr. Burns said he did not think there was any justification for the statement with regard to cancer. The regulations passed a year ago gave sufficient power to deal with any unsound meat attempted to be brought into this country, as had been discovered in this particular case. With regard to the importation of frozen carcasses from which the lymphatic glands had been removed to conceal the presence of tuberculosis, Mr. Burns said that practically it was only in the case of pigs that the entire carcass was imported as frozen meat. The new regulations dealt with cases where the carcass of a pig was imported without the head in its natural state of attachment and was without the lymphatic glands about the throat and any other part of the carcass in their natural position. In any such case the medical officer of health and the sanitary authority were required to take such action as would secure that the meat would either be exported or destroyed. The powers conferred by the regulations were, so far as he was aware, duly exercised, and they appeared to be sufficient to meet the object in view. In answer to Mr. Vincent Kennedy last Monday Mr. Burns said that he had no information as to the re-exportation during the years 1906-7-8 of meat alleged to be unsound. The new regulations did not come into operation until January 1st, 1909. Any destruction of foreign meat under them must

take place under the supervision of the medical officer of health, and after the importer had failed to comply within twelve hours with a notice from the sanitary authority requiring him to give a written undertaking to export the meat at his own expense or prove before a justice that it was not intended for human consumption. If the importer undertook to export the meat, it rested with the sanitary authority to satisfy themselves that the exportation took place. If within three days after the receipt of the undertaking the meat was not exported, the sanitary authority must cause it to be destroyed. The meat need not necessarily be dispatched to the place from which it was originally sent. It was not required to be marked in any way before it was re-exported. In the majority of cases it was taken to the local dust destructor.

The Milk Question.—Last week, on the motion for the second reading of the London County Council (General Powers) Bill, there was an interesting discussion on the milk clauses. Mr. Courthope moved the rejection of the bill in order to denounce the milk clauses and secure their withdrawal. He finally succeeded in his object by getting a promise of their withdrawal before the bill was read a second time. His main argument was that the eleven clauses dealing with milk gave too drastic powers to London as compared with other local authorities. They gave the London County Council power to interfere in any dairy county. A general enactment was wanted and not a special law. At present over 300 authorities did nothing, and in the interests of public health a general law was required. After the rejection had been seconded, Mr. Guinness defended the clauses as necessary for public health. Referring to infantile mortality, he said that in towns 22 per cent. of it was due to diarrhoeal disorders, while in the country it was only 15 per cent. In children fed from the breast or on specially selected milk this cause of mortality was greatly lessened. He quoted the medical officer of health of Islington to the effect that dung was found in 99 per cent. of the samples taken. The County Council wanted powers to take samples at railway stations so as to discover the farms from which impure milk came. Mr. Burns said the Government could not support the milk clauses of the bill because they only partially remedied the evils. The bill to be introduced shortly by the Government would do more and would give larger powers generally over the whole kingdom. He admitted the magnitude of the evils and appealed to the House not to deal with it piecemeal, but to leave out these clauses as the Milk Bill must be passed. He said the Commission on Tuberculosis had made a number of recommendations which could not be ignored. It had declared that human and bovine tuberculosis cannot be distinguished, that no doubt child tuberculosis is the direct result of the bacillus of bovine tuberculosis, and that cow's milk which contains bovine tubercle is clearly the cause of fatal tuberculosis in man. Mr. Guinness then agreed that the clauses should be dropped, but Mr. Dickenson pointed out that a strong Government bill was sure to be fought and possibly rejected or seriously modified. Mr. Cooper also strongly deprecated the dropping of the clauses. The President of the Local Government Board took upon himself a most serious responsibility in suggesting this course unless he could secure not only the introduction of a strong bill, but its passage into law. He argued that a strong bill must meet much opposition: for the moment London introduced strong clauses, twelve members representing agricultural constituencies put down amendments to destroy them. The question had been before the House for five or six years; nothing was done under the late Government, and so far nothing under this, except a promise of a bill which might not be accepted in the Upper House. In the end, after a characteristic outburst from Mr. Lupton—who declared his disbelief in children being killed by milk, or that there was any evidence that tuberculosis was conveyed through milk—the bill was read a second time, on the understanding that the milk clauses were to be dropped.

The Notification of Infectious Diseases.—Mr. Tyson Wilson asked the President of the Local Government Board whether, seeing that during the year 1907 the deaths occurring from three infectious diseases that are not

compulsorily notifiable were 30,249, while the deaths from ten infectious diseases that are compulsorily notifiable were only 8,629, he could see his way to include the three diseases that are not compulsorily notifiable in the list of those that are, or, otherwise, remove some of those diseases that had to be notified from the list. Mr. Burns said he was not empowered by the Infectious Diseases (Notification) Acts, 1889 and 1899, to adopt either of the courses suggested. It was, however, competent for the sanitary authority of any district, with the approval of the Local Government Board, to order that the Act of 1889 should apply in their district to any infectious disease other than a disease specifically mentioned in that Act, and the Board had given its approval to orders made by various sanitary authorities extending the Act to the three diseases referred to in the question. The Acts did not apply to London, but there were provisions similar to those contained in them in the Public Health (London) Act, 1891.

Death from Glanders.—In answer to a question last week, Sir Edward Strachey said that the Board of Agriculture was aware of the unfortunate circumstances concerning the death from glanders of Charles Edward Davis. The attention of the London Council Council was directed to the case, and the horses in the stables where the man was employed were at once inspected. Glanders was found to exist, and the necessary steps were being taken to deal with the outbreak. The County Council had taken the matter up with great energy, and the Board was satisfied that it was taking every necessary precaution.

Navy (Medical Branch).—On Tuesday Mr. Bramsdon asked the First Lord whether his attention had been called to the case of the four head ward masters who were the only warrant officers in the entire medical branch of the Royal Navy; was he aware that ordinarily they were unable to attain that rank until roughly 40 years of age, when nearing the end of their service, whilst all other branches of petty officers, with the exception of school masters, for whom special provision was made, were able to get promotion to the warrant rank from the age of 25 and upwards, but none after 35, and that their pay consequently was only equal to that of the young warrant officers of other branches; and whether he would give consideration to this class. Mr. McKenna replied in the affirmative.

The Committee on the Midwives Act.—In answer to Mr. Clynes, who asked if the Departmental Committee could be made to include a representative of the National Association of Midwives, Mr. Burns said that he had been in communication with the Privy Council on this subject, and he found that, in the opinion of the Lord President, the Committee was sufficiently large for the practical objects of the inquiry, and that these would not be served by the addition of representatives of special interests. Their views would be properly considered in connexion with any evidence that might be given.

Water Supply.—Last week, in answer to Mr. Courthope, the Prime Minister said that the honourable member was no doubt aware of the recommendations made by the Royal Commission on Sewage Disposal in their third report with regard to the waste of water and its abstraction from one district for distribution in another. These recommendations had received the consideration of the President of the Local Government Board in connexion with the bill relating to Rivers Pollution and Water Supplies which he hoped to introduce this session. In these circumstances, the appointment of a further commission, as suggested, seemed to be inexpedient.

Street Accidents (Doctors' Fees).—Mr. Weir asked the Secretary of State for the Home Department whether, having regard to the fact that doctors receive 3s. 6d. only for attending casualties in the streets, whereas veterinary surgeons receive 10s. 6d. for attending injured horses, he would take such steps as may be necessary to secure the more adequate remuneration of doctors. Mr. Gladstone said that the cases were not parallel. The fee of 3s. 6d.

(7s. 6d. after 7 p.m.) paid to medical men represented as much, or more, than the ordinary practitioner would receive for attending patients of the class whom he was called to attend by the police. For exceptional cases, a special fee was sometimes paid. Moreover, the majority of these fees were paid to divisional surgeons, who received them in large numbers, and were, besides, paid salaries from the Police Fund. Veterinary surgeons had far fewer cases to attend, and had generally greater distances to travel. He was satisfied that the medical men in question did receive "adequate remuneration" for the services they rendered.

Death-Rates in England, France, and Germany.—In answer to questions put by Mr. Lylph Stanley, Mr. McKinnor Wood said that the following were the figures for the year 1907:

Country.	Deaths per 1,000.
England and Wales	15.0
France	20.2
German Empire	18.90
City.	
London	14.6
Paris	18.5
Berlin	15.4

With reference to deaths of infants under 1 year, the following were the figures for the year 1907:

Country.	Deaths per Cent.
England and Wales	11.8
German Empire	17.6

In the case of France he had no later figure than that of 1906, which was 14.3.

City.	Deaths per Cent.
London	11.6
Paris	10.5
Berlin	16.3

Vaccination Prosecutions in Ireland.—Mr. John Robertson called Mr. Birrell's attention on Tuesday to a case of prosecution, and asked for some legislation to enable conscientious objectors in Ireland to avoid prosecution, as in Great Britain. Mr. Birrell answered that in December last the guardians' solicitor obtained an Order at Petty Sessions, under Section 147 of the Public Health Act, to compel Mr. Francis Irvine to have his two children vaccinated within a month. The Local Government Board had no means of knowing whether notice had previously been served on him. That was a point for the consideration of the magistrates. Having failed to comply with the magistrates' order, Mr. Irvine was fined 2s. 6d. and 5s. costs at Petty Sessions on February 19th, as stated. He was informed that legal proceedings were usually instituted against a defaulter under the Vaccination Acts before steps were taken under Section 147 of the Public Health Act, and this course was presumably followed in the present case. The number of conscientious objectors to vaccination in Ireland was very small, and they were not, he understood, generally subjected by guardians to repeated prosecutions. He could not undertake to introduce legislation on the subject.

The Island of Lewis.—Mr. Weir asked what was being done to improve the sanitation of the townships which had been reported to be dangerous to the public health. Mr. Ure replied that since the publication of the report in question there had been steady progress in the sanitary improvement of the crofters' houses. The construction of houses on new sites was a solution which presented many administrative and financial difficulties, and he had not found it possible to approach the Treasury on the matter; but this and other questions affecting administration in the Lewis were constantly before him.

The Oaths Bill to facilitate taking the oath with uplifted hand was read a second time late on Tuesday night, and will in due course be considered by a Standing Committee.

Vivisection.—Mr. Hodge introduced a bill for the total abolition of vivisection on Tuesday, and put down the second reading for May 29th.

India.

THE BOMBAY MEDICAL CONGRESS.

On February 22nd this great congress was opened by Sir George Clarke, F.R.S., the Governor of Bombay, who delivered an eloquent address reviewing the progress of medical research in India. The commemorative medal was then presented by him to several distinguished visitors, including Professor Ronald Ross, and Professor Musgrave of the Philippine Islands. At a later meeting a medal was also presented to Professor Shiga from Japan, who had not been able to be present at the opening meeting.

The five sections held both morning and afternoon sessions on three days, and in some cases a morning session on the fourth; the afternoon of that day the members were invited to visit the Parel laboratory. The number of members was very large, including over 100 I.M.S., a few R.A.M.C. officers, and numerous Parsee and Indian practitioners, leave having been granted to many assistant surgeons to enable them to attend. Every province of India and all branches of medical science were well represented; there was a good attendance at all the sections, while certain subjects attracted very large crowds, so that the proceedings were frequently quite enthusiastic. The meetings were all held in the magnificent University buildings, which form one of the main architectural features of this beautiful city, while immediately in front of them was placed the exhibition, a tent in which was accommodated the Sanitary Section. The whole of the arrangements were most admirably organized by the Secretary, Lieutenant-Colonel W. E. Jennings, I.M.S., to whom the thanks of all were due.

The Work of the Sections.

The great attraction on the first day was the discussion on antimalarial measures in India, introduced in an exhaustive paper by Professor Ronald Ross, F.R.S.; it was followed by other papers by Captain Christophers and Dr. Bentley on their investigations on blackwater fever, and by Major S. P. J. James, I.M.S., on the great prevalence of malaria in Mian Mir cantonment last year in spite of vigorous antimalarial operations. The latter paper in particular gave rise to a very keen discussion, during the course of which it appeared that the very heavy rains of last year had much to do with the admitted failure of the antimalarial operations, but that better results might be obtained if drainage operations were added to the previous programme. The generally expressed opinion was that in most Indian conditions quinine prophylaxis was more practicable than mosquito destruction. On the second day the papers on plague prophylaxis gave rise to an equally interesting and keen debate, the relative importance of recrudescence or reimportation as the cause of the repeated yearly outbreaks in the Punjab being the main subject of contention. In the first section the discussions on the treatment of cholera and on dysentery attracted considerable attention, and that on the treatment of snakebite was also of considerable interest. Another very important contribution was one by Dr. Row on the development of the parasite of Delhi boil into a flagellate stage, precisely parallel in its general characters to that of the *Leishmania donovani* of kala-azar, although it appeared to differ in some details, so that it will probably prove to be a different variety of the genus. In the Surgical Section the subject of operations for cataract was the most important dealt with, a number of papers being read in support of the intracapsular operation of Smith of Jullunder.

Pathological Section.

One of the most interesting and best organized of the sections was the pathological; the exhibition, which contained a large number of microscopical preparations, illustrating the more important researches in tropical medicine, including Row's Delhi-boil cultures, having been arranged. A number of coloured drawings of skin and bowel diseases were shown from the Calcutta Medical College Museum, and a good collection of snakes by Major Wall, I.M.S. Captain Cunningham, I.M.S., deserves great credit for the excellent collection he had got together from all parts of India.

Conversazione.

On the second evening a series of lantern lectures on medical subjects of twenty minutes each were given, and were attended by a very large number of the members and their friends. The subjects treated included the nascent treatment of leprosy, the parasite of Delhi boil, blood sucking insects, snakes and fevers, etc. This meeting, which was a great success, was held in the grounds of the exhibition, and intervals were allowed between each lecture, social and instructional opportunities being thus combined.

Indian Medical Service Dinner.

Well over one hundred officers and guests sat down to the dinner on the evening of the last day after the visit to Parel Bacteriological Laboratories. The Governor of Bombay was present, and Surgeon-General Sir Gerald Bomford took the chair. The speeches were few but good, the chairman pointing to the great advances in research work in India since the last congress in Calcutta fifteen years ago. Professor Musgrave, from the Philippines, returned thanks for the visitors, and struck the same note, while Professor Ross was also called on to speak.

The gathering has thus been a notable one in many respects, and it is to be hoped it will be repeated at a much shorter interval than the last.

Natal.

IMPORTED COOLIE LABOUR.

Two of the principal newspapers published in Durban, the *Natal Advertiser* and the *Natal Witness*, contain in their issues for the first week of February copies of correspondence between a medical officer lately in the employ of the Indian Immigration Board and the Chief Secretary to the Government relative to his dismissal from his appointment, and in each case the editors of these newspapers, after considering the facts, call for explanations from Government. These in one form or another will doubtless be given during the course of the approaching session of the Natal Legislature; but meantime, it may be said, that the facts revealed are sufficient in themselves to condemn the arrangements under which medical officers in charge of indentured coolies do their work. About eighteen months ago, by way of rendering them less subject to the caprices of those who are the common employers alike of themselves and of the coolies, these officers were given by the Legislature a right of appeal to the Governor in Council should their dismissal be proposed by the Indian Immigration Board. This right was exercised for the first time in the case which is the subject of the correspondence and comments mentioned, and the fashion in which the appeal was treated is instructive. The medical officer was at first merely informed that the Governor in Council had rejected his appeal, but subsequently extracted the information that what had really happened was that the Government made certain "recommendations" to the Indian Immigration Board respecting the proposed dismissal, that this board declined to fall in with them, and that the Government then subsided. The intention of the law was undoubtedly that the Government should impartially review the decisions of the board, and either confirm or set them aside, according to its view of justice; by merely making "recommendations" and allowing the board to fall in with them or otherwise, as it pleases, the right of appeal seems to be reduced to a farce. The circumstances of the case render the treatment of the appeal all the more striking. The officer in question was given six months' notice at the beginning of 1908, but before the six months was up the board withdrew the notice of dismissal and offered him a better-paid appointment of the same character in another district. This offer the officer did not see his way to accept, and thereon he was redissmised without explanation of any kind. It is clear from this sequence of events that any ground of complaint which the board may have had against this officer can scarcely have been of such character as to justify his dismissal, and consequently that the law conferring the right of appeal has failed in its object. This is the more important when it is remembered that

that right was accorded less in justice to medical men than for the sake of their coolie patients. It was tardily recognized, in short, that the latter were likely to suffer if the board could exercise an uncontrolled power of dismissal over any medical officer whose ways of dealing with coolies did not chime in with his employers' views of what was convenient to his interests.

The net outcome of the incident is to strengthen the hands of those who for a long time past have been anxious to see the status of medical officers in charge of imported labour completely changed. Finally, as a possible factor in the fate of this particular officer, it may be mentioned that he was conspicuous for his scientific zeal in tracing certain obscure maladies among the coolies to their true source. He was one of the first to show that this was ankylostomiasis infection, and that this grave disease was being imported into the colony by coolie-bearing ships and spreading among the general population. This revelation naturally caused considerable alarm, and was most inconvenient to the board and its estate-owning constituents, for, besides involving more or less expense, it helped on the movement in favour of appointing a Commission to consider the question of the propriety of allowing the importation of coolie labour to continue. That Commission is now sitting, and its terms of reference specifically include consideration of the medical arrangements for the care of coolies working on estates. It was, indeed, allegations made by a medical officer on resigning his appointment under the Immigration Board last autumn which gave the local press and public a weapon by which to force an inquiry upon Government. The party representing the interests of estate owners and in favour of imported coloured labour is powerful, so the final outcome of the inquiry is doubtful, but it is to be hoped that in future medical officers who look after coolies will do their work as Government officers and not as privately employed officials; or, in other words, that Natal in this respect will fall into line with all other British coolie-importing countries.

Since the Government of Natal does not enjoy a very desirable reputation as an employer of medical labour, medical officers of the Indian Immigration Board may possibly be not anxious to change masters, preferring the frying pan to the fire. There are, however, only some twenty of them in all, at least half being already Government officials as well as medical officers in the employ of the Immigration Board, and in any case, even should they prefer to remain as they are, general and not individual interests must necessarily be considered. When an important Government official, such as the Protector of Indian Immigrants, frankly condemns, as recorded in our issue for September 19th, 1908, the present system of appointing coolie medical officers as unsound in principle and detrimental to the coolies in their charge, and when, not regarding them as free agents, but as servants of the estate owners, he publicly declines to ask for any reports from them, it is clear that there must be a *prima facie* case for investigation. Furthermore, he has adopted the same course in reference to the year 1908, and meantime information received by this JOURNAL from a variety of sources all tends to show that the attitude which he has adopted—doubtless by way of bringing things to a head—is well founded, and that the view which he has expressed—namely, that to carry out their duties satisfactorily medical officers in charge of coolies should, as in all other colonies, be made independent of estate owners—cannot be controverted. When the decision of the Protector of Indian Immigrants was recorded in these columns at the date mentioned, note was also made of the case of a medical officer who, "finding his position intolerable," had recently resigned his appointment, and the opinion was stated that an inquiry into the general subject of the medical care of coolies ought to be held. This addendum has elicited the following communication:

We, the undersigned, being Indian Medical Officers of Circles in Natal, were surprised to find a statement in the BRITISH MEDICAL JOURNAL of 19th September, 1908, implying that we were dissatisfied with our positions under the Indian Immigration Trust Board of Natal.

We entirely object to this statement, and wish to protest against it. We have not found our positions "intolerable," but, on the contrary, we have always been treated with due consideration and courtesy.

This letter, which, curiously enough, was not sent off

until four months after the publication of the passage in question, bears the signatures of fifteen of the medical officers. The rest, it may be assumed, considered it somewhat foolish to "protest" against a statement which had not been made. Why the document was originally circulated for signature is another question, and in any case the contained expression of satisfaction does not outweigh the evidence as to the real feeling within the service which has been otherwise received; nor does it lessen our belief that a complete change of status in the case of coolie medical officers is desirable alike in the interest of the indentured labourers, the general public, and the medical officers themselves.

Sydney.

[FROM OUR SPECIAL CORRESPONDENT.]

NEW SOUTH WALES BRANCH OF THE BRITISH SCIENCE GUILD.

A MEETING was held last December to inaugurate the New South Wales Branch of the British Science Guild. The chair was taken by Dr. F. A. Bennet, who, after apologizing for the absence of Sir Normand MacLaurin, explained that the meeting had been called for the purpose of forming a science guild in Australia. The objects of the guild were:

(1) To bring together as members of the guild all those throughout the Empire interested in science, in order that, by joint action, they might convince the people of the necessity of applying the methods of science to all branches of human endeavour, and thus to further the progress and increase the welfare of the Empire. (2) To bring before the Government the scientific aspects of all matters affecting the national welfare. (3) To promote and extend the application of scientific principles to industrial and general purposes. (4) To promote and extend scientific education by encouraging the support of universities and other institutions where the bounds of science are extended or where new applications of science are devised.

The Chairman referred to the fact that for years it had been recognized that Great Britain was losing ground, while America and Germany were making great strides. England did not produce enough scientifically-trained young men to second the efforts of the scientific heads of industries. America was alive to the necessity of making science the basis of all industrial endeavour.

Dr. Walter Spencer submitted the report of the organizing commissioner. He referred to the enthusiasm which attended the formation of the British Science Guild when all the leading statesmen, scientists, philosophers, and manufacturers of the empire met together. He contrasted the Germany of sixty years ago with the great empire of to-day. The guild had granted £10 towards the expenses of formation of an Australian Branch. So far all the expenses of the Branch had only amounted to £5 10s. A special vote of thanks was accorded to Dr. Spencer for his work in organizing the Branch. Sir Normand MacLaurin was elected President, and several medical men were elected Vice-Presidents. Dr. Walter Spencer was elected treasurer and secretary, and also chairman of the sub-committees.

UNIVERSITY REFORM.

The Senate of the University of Sydney has recently been considering the question of university reform. Two proposals have been considered. The one is to do away with the principle of life tenure of office by senators; the other is that a rector should be appointed at a salary, his only duty being to govern the University. After considerable discussion of these two questions, it was resolved to appoint a committee to consider them further. The committee appointed was: Sir Normand MacLaurin (Chancellor), Dr. Cullen (Vice-Chancellor), Judge Backhouse, Professor MacCallum, Mr. Leverrier, and Mr. H. C. L. Anderson. The committee will probably bring within the scope of its inquiry the whole constitution of the University, and it is considered very likely that it will recommend some change in the life tenure. In consequence of the death of Sir Arthur Renwick there is a vacancy on the Senate, and two candidates have been nominated, Drs. C. Purser and Camac Wilkinson. Both candidates are strong on the need of university reform, and are in favour of a modification in the tenure of office by senators.

STATE CHILDREN.

The annual report of the State Children's Relief Board has been presented to Parliament. The President, the Hon. Dr. C. K. Mackellar, signs the report, which states that the total number of children under departmental control at the date of the report was 7,835, representing an increase of 786 over the number for the previous year. Of these, 4,202 were placed out apart from their mothers, and 3,633 with their mothers. The proportion of boarded out children to the population of the State was 4.95 per 1,000. The proportion of children boarded out apart from their parents stood at 2.65 per 1,000. For several years past this proportion had remained stationary, and represented the class which, under the barrack system, would be maintained in orphan schools. The proportion of children boarded out with their own mothers had risen unusually, being 2.29 per 1,000, as against 1.96 per 1,000 in the previous year. The increase was attributed to the greater cost of living—due to the tariff—compelling an additional number of mothers to apply for aid on behalf of their children. The expenditure for the entire services of the department was £75,910. Of this total expenditure, £37,685 was for maintenance, cost of clothing, medical fees, and proportion of travelling expenses for the children boarded out apart from their parents. Deducting the contributions by parents, the actual cost to the State of each child was £15 10s. 2d. During the year 418 boys and 304 girls were discharged from control, leaving under supervision at the end of the year a total of 4,202 children. The total admissions during the year exceeded those during 1907 by 204, and the total discharges was greater than that for the previous year by 160. These figures, to a very large extent, indicate the operations of the children's courts so far as the number of admissions is concerned; the increased number of discharges show the policy of the board, which is to send the children home again as soon as improvement has been manifested in their conduct.

Canada.

[FROM OUR SPECIAL CORRESPONDENT.]

MILITIA MEDICAL OFFICERS OF CANADA.

The annual meeting of the Association of Medical Officers of the Militia of Canada, held at Ottawa on February 25th and 26th, under the presidency of Colonel Ryerson, M.R.O., was well attended. Addresses were given by the president and by Major-General Sir Percy Lake, K.C.M.G., Inspector-General, and the following officers were elected for the ensuing year:

President: Lieutenant-Colonel H. S. Birkett, Montreal.

Vice-Presidents: One from each military district—Major Rankin, M.P.; Lieutenant-Colonel G. S. Rennie, Major Kilborne, Major E. R. Brown, Captain Williams, Major E. A. le Bel, Lieutenant-Colonel Murray MacLaren, Lieutenant-Colonel Currie, Lieutenant-Colonel Blanchard, Captain McTavish, Lieutenant-Colonel Jenkins, Captain S. W. Hewitson.

Secretary-Treasurer: Lieutenant T. H. Liggett, Ottawa.

The following resolution, of which Lieutenant-Colonel Jones, P.A.M.C., had given notice at the last annual meeting, was adopted:

That this Association of Medical Officers of the Militia of Canada expresses its approval of the scheme of forming in Canada an association having for its object the development of Ambulance and Red Cross work in the Dominion.

A number of papers were read, including one entitled, Impressions of a Month at the Royal Army Medical College, London, by Lieutenant-Colonel Fotheringham, P.M.O., M.D.; another on the Routine Work of the Sanitary Officer at Camps of Instruction, by Captain Clark, P.A.M.C.; and another on the Trek of a Field Ambulance, by Major T. B. Richardson, A.M.C.

The next annual meeting of the association will be held at Ottawa on February 24th and 25th, 1910.

PROPRIETARY DRUGS.

Under regulations adopted by the Government of the Dominion of Canada with regard to the manufacture and sale of patent or proprietary medicines, all such patent or proprietary medicines in the hands of manufacturers or dealers shall bear the stamp of the Department of Inland Revenue, but this stamp will not be provided for drugs or

medicines containing cocaine or its derivatives; under the Patent Medicine Act importation or sale of such after April 1st, 1909, is prohibited.

SPITTING IN RAILWAY CARS.

The railways of Canada have all, at the solicitation of the Montreal Board of Trade, been sent copies of the draft order of the Board of Railway Commissioners regarding spitting in cars, and will appear to submit their views. The draft order requires every railway company within three months—

1. To properly clean and disinfect and thereafter to properly keep clean and disinfected its passenger cars, stations, and waiting rooms, in order to prevent dissemination of tuberculous or other infectious or contagious diseases.

2. To cause printed notices to be placed and maintained in each of its passenger coaches, one in each end of the car, and in some conspicuous place in each of its stations and waiting-rooms, prohibiting the practice of spitting in the said cars, station, and waiting-rooms, except in proper receptacles provided for the purpose, and prescribing a penalty for violations thereof.

3. That every such railway company be liable to a penalty of a sum not exceeding fifty dollars for every failure to comply with the foregoing regulations within the time for their coming into force and thereafter.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

MANCHESTER AND DISTRICT.

THE EPIDEMIC OF INFLUENZA.

THE epidemic of influenza is so widespread in Manchester at present that the medical officer of health, Dr. Niven, has thought it necessary to have large bills posted up all over the district, giving hints for prevention and treatment. Last week 8 deaths were notified as directly due to influenza, and the fatal cases of pneumonia were especially numerous. Last year the highest figure for deaths in one week from pneumonia was 47, but last week 57 were recorded. In many cases of influenza this year typhoid characteristics are prominent, and most patients are troubled with a constant tickling cough. The acute stage often lasts from ten to fifteen days, and is followed by considerable weakness and depression. Dr. Niven draws particular attention to the need for isolation, especially in the case of first attacks in the household. He says that persons attacked "should not on any account join assemblages of people for at least ten days from the commencement of the attack." There is fear that these directions about isolation will be largely disregarded, in spite of the fact that every one knows perfectly well how infectious the disease is, and nothing short of compulsion will procure proper isolation. Next to isolation, perhaps, the most important suggestion given by Dr. Niven is that "discharges from the nose and mouth should not be allowed to get dry on the pocket handkerchief or inside the house or workshop. They should at once be collected on paper or clean rag and burned, or, if this cannot be done, the paper or rag should be dropped into a vessel of water, while infected articles and rooms should be cleansed and disinfected." Other valuable suggestions for prevention are given which afford a good example of the way in which municipal authorities may proceed in preventive treatment for the whole community, in contrast with the so-called curative treatment for paupers only with which boards of guardians seem bound to be content.

A DOUBTFUL CAUSE OF DEATH.

A somewhat unusual case was investigated last week at Pendlebury which may have the effect of still further lengthening the list of occupation diseases for which compensation may be claimed. It appears that an elderly man who had been for twenty-one years a sexton at Pendlebury, while engaged in digging a new grave in the churchyard accidentally opened with his pick an old brick drain from which a most offensive effluvia came. He complained the same night of feeling ill, and soon began to suffer from severe diarrhoea. It was found necessary to call in Dr. David Owen, of Ilrams-o'-th'-Height, who found him suffering from diarrhoea and pneumonia, from

which he eventually died. Owing to the unusual circumstances, the coroner was informed, and thought it right to hold an inquest, with a *post-mortem* examination. At the inquest Dr. Wright, of Ancoats Hospital, said that he had made a *post-mortem* examination, and agreed with Dr. Owen that the cause of death was acute pneumonia. It was quite possible that the diarrhoea which commenced the illness might have been caused by the bad effluvia, and in favour of this was the fact that the deceased had had similar attacks before following exposure to similar exhalations. Dr. Owen said that on February 22nd he found deceased suffering from diarrhoea and pneumonia. After a few days the case seemed somewhat favourable, but another attack of diarrhoea set in, and he gradually sank. Dr. Owen had known the man for ten years, and had attended him before for diarrhoea. On one occasion he had called in the late Professor Leech of Manchester in consultation, and they agreed that there was some reason for thinking that the noxious emanations from old graves might have caused a malignant form of diarrhoea, and the man was advised to give up the occupation of gravedigger. Witness entirely agreed with the evidence from the *post-mortem* examination that the cause of death was pneumonia, but he referred to several authorities to show that cadaveric exhalations were recognized as a cause of disease and death. In the *Nomenclature of Diseases*, issued by the Royal College of Physicians, "putrid exhalations" were given in the list of poisons. A member of the jury said he thought that death had been caused by diarrhoea set up by the bad smells, but the coroner pointed out that the doctors' evidence only showed that that was possible, though it could not be proved, and the jury would be treading on dangerous ground; the *post-mortem* examination exactly tallied with what Dr. Owen had certified—that death might have been caused by the exhalations. Ultimately a verdict was returned of death from natural causes. The case is interesting not only from a medico-legal point of view but scientifically, and may be noted in connexion with an investigation that is now going on in Manchester as to the effect of sewer gases on the public health.

SMALL-POX INFECTION FROM COTTON.

The possibility that small-pox can have been conveyed to England from Egypt by means of raw cotton has been suggested by the medical officer of health for Bolton, where two sporadic cases have recently occurred. A cotton worker was found to be suffering a few weeks ago, and no definite source of the infection could be found after the strictest investigation. A second case, also in a cotton worker, occurred soon afterwards, and it is understood that the two cases had had no connexion with one another, and were employed at different mills. In Stockport also a case has occurred in a cotton worker. Three cases altogether have been found in Stockport, but it is known that two had been in contact with the first. As far as can be ascertained, no further case has occurred, and after the measures that have been taken, it is not likely that the disease will spread. In the year 1901 a sporadic case occurred in Stockport, and Dr. Meredith Young, then medical officer of health for Stockport, expressed the opinion that the disease had been conveyed in cotton. At that time it was found that there was a mild epidemic of small-pox among the natives employed on the cotton plantations of Texas and the Southern States where the cotton came from. There had been no case in the town for fully a year previously, and the man who was attacked was engaged in opening the bales and feeding the raw cotton into the machines. At the present time some of the cotton comes from Egypt, and it seems that small-pox is somewhat more prevalent there than usual. It is the custom of the cotton workers, in manipulating it, if a strand should get broken to piece it up by wetting it with saliva, and any infective material might thus readily get into the mouth. As no very effective means are taken to cleanse the cotton before arrival in England, and as many of the cases of small-pox may be slight and easily overlooked among the natives on the plantations, even if the present cases cannot be proved to have been actually caused in this way, it is evident that some danger may exist. The bales of cotton are so tightly packed, as a rule, that it is hardly likely that any infective material would be sufficiently exposed to the air to cause any great attenuation of the virus.

NEWCASTLE-UPON-TYNE.

MEDICAL INSPECTION OF SCHOOL CHILDREN.

The increased work thrown upon Dr. George Foggan, the Medical Inspector of Schools, has rendered necessary the appointment of an assistant—Dr. R. Rutherford. Every facility has been afforded to these gentlemen by the Education Board as regards provision of office, rooms, and clerical assistance.

MATERNITY HOSPITAL.

At the annual court of governors of the Newcastle Maternity Hospital, presided over by the Lord Mayor of the city, it was reported that 1,108 outdoor cases were attended mainly by the students and nurses, while 227 patients were admitted into the hospital during 1908—an increase of 222 outdoor and 16 indoor cases compared with the numbers for 1907. Negotiations are in progress for the sale of the present site and the purchase of another for a new hospital, which is considered to be a necessity. During 1908 three examinations were held in the hospital under the regulations of the Central Midwives Board.

EDINBURGH UNIVERSITY CLUB.

The members of the Edinburgh University Club held their annual dinner in Tilley's Rooms under the presidency of Dr. W. S. Campbell on March 12th. The vice-chairs were occupied by Dr. James Smith, of Ryton, and Dr. Goudie, South Shields. The guest of the evening was Professor Francis M. Caird. Sixty gentlemen sat down to dinner. After the loyal toast had been honoured, the President in a happy speech proposed "Alma Mater," and in coupling with it the name of the guest, extended a hearty welcome to Professor Caird. Before sitting down the company sang "Gaudemus." Professor Caird had a most cordial reception, and to all assembled his reply, which was full of anecdote and of interesting reminiscences of Edinburgh professors, teachers, and infirmity officials, was a source of extreme delight, heightened when Professor Caird brought his interesting remarks to a close by his singing two verses of an old song. To Dr. Hume was entrusted the toast of "Sister Universities," and by none could it have been better rendered. Sir Thomas Oliver responded. In a very appropriate speech the health of the President was proposed by Dr. Bunting, who alluded to the important part Dr. Campbell had played in the foundation and development of the club. Under the genial guidance of the chairman a most pleasant evening was spent. The toast list was short, and this gave the meeting a distinctly social character, and allowed more opportunity for song and conversation. The musical part of the proceedings was much appreciated. To the pleasure of this Professor Caird, who was quite at home among friends and old fellow students, in no small degree contributed. Much of the success of the banquet was due to the excellent arrangements made by the honorary secretary, Dr. T. Gowans.

WEST YORKSHIRE.

THE SANITARY CONDITION OF HARROGATE.

The Sanitary Committee of the Harrogate Town Council has lately had under consideration a report by Dr. Spencer Low to the Local Government Board on sanitary matters as affecting the borough. As a result of this, certain recommendations have been formulated by the Sanitary Committee, which were brought before the Town Council on March 8th, and after considerable discussion were eventually adopted. These recommendations were:

1. That the corporation should take steps to appoint two additional men to assist the inspector of nuisances in an inspection of all house drains in the borough.
2. That the corporation should make application to the Local Government Board for an order putting in force in the borough Section 25 of the Public Health Acts Amendment Act, 1907, with respect to the forming, flagging, asphaltting, or paving of yards to dwelling-houses, for the effectual drainage of the subsoil, or surface of the yards, to a proper outfall.
3. That notices should be given to the owners of two disused underground cellars and warehouses that the premises must not be again used as backhouses.
4. That a subcommittee be appointed to seek a conference with subcommittees of the rural and urban district councils of Knaresborough with a view to the three authorities appointing

a joint meat, milk, and cowsheds inspector for the whole area of the three districts.

5. And that a subcommittee of the corporation inquire into the advisability of appointing a medical man to devote the whole of his time to the duties of medical officer of health and education medical officer for the borough.

Owing to the popularity of Harrogate as a residential and health resort, its sanitary condition is not only a matter of local but of national concern; it should be above suspicion.

THE TREATMENT OF PHTHISIS IN THE BRADFORD WORKHOUSE.

The Bradford Board of Guardians has recently had under consideration the danger to the general inmates of the hospital from the presence amongst them of cases of phthisis. The guardians on February 24th had 120 cases of phthisis and only proper accommodation for 79, so that 41 cases were in the ordinary hospital wards. They determined to erect a temporary structure near the present premises to accommodate these patients, but their plans have been vetoed by the Local Government Board for the following reasons:

1. Owing to the proximity of the proposed building to the boundary of the site and to the neighbouring dwellings.
2. To the impossibility of securing a favourable aspect.
3. To the impossibility of arranging a building on the limited area so as to secure sufficient cubic space for the number of occupants and of dividing the building into sections so as to form smaller groups of patients in the wards and of giving the benefit of some open-air treatment.

PHTHISIS AMONGST STONE WORKERS.

Dr. Edwards, M.O.H., at the meeting of the Southowram (Halifax) Urban District Council, held on March 2nd, submitted his annual report, and drew special attention to the death-rate from phthisis. Southowram, situated on the top of Beacon Hill, and considered one of the healthiest parts of Halifax, had a very high death-rate from phthisis. The population of the district is about 3,072, and the chief industry quarrying. Dr. Edwards attributes the prevalence of the disease to stone dust, and believes that the disease might be considerably diminished if the workers could be persuaded to wear some kind of respirator to prevent the inhalation of the stone dust. He recommends that pulmonary consumption should be included amongst the notifiable diseases.

LIVERPOOL.

A NEW MATERNITY HOSPITAL.

At the annual meeting of the Ladies' Charity and Lying-in Hospital it was pointed out that the present hospital, with about twenty beds, was inadequate to meet the requirements of a large city like Liverpool with its unusually large proportion of poor. Sir William Hartley, in speaking to the adoption of the annual report, announced his intention of erecting a new maternity hospital, to provide bedroom accommodation for seventy-five persons—say, fifty patients and twenty-five staff and pupil midwives. The cost is to be £15,000, including the building, furniture, and equipment in every particular, with passenger lift and suitable laundry. The committee is to provide the site, and a sum of £20,000 is to be raised as a maintenance fund, to be expended during the first fifteen years. It is expected that the construction of the hospital will take about eighteen months. Sir William Hartley expressed the hope that the hospital would become a great teaching centre, and that many medical students would get their maternity training there. He desired a medical woman to be included in the resident staff, and expressed the opinion that it was in the interest of the hospital and also of the community that the medical staff should retire at a somewhat earlier age than has been usual hitherto, and thus give an opportunity for a larger number of medical men to gain experience in the new institution. On this suggestion it may be observed that the retiring age has recently been fixed at 60, the limit which holds at the Royal Infirmary, the Northern Hospital, and the Stanley Hospital. Sir William Hartley's munificent support of the medical charities of Liverpool, and his enlightened interest in their welfare, are universally acknowledged, but there can be no doubt that by the present gift he has not alone done an

immense service to the poor of the city, but by providing a wider field and an adequate provision for the teaching of practical midwifery has conferred a great boon on the medical school and the university.

MEDICAL OFFICER TO THE POLICE.

It is a matter of great regret that the movement started in the local Divisions to induce the city council to grant better terms to the medical officer to the B Division of the police has not been successful. Dr. W. J. Bennett Jones has been appointed at a salary of £60 per annum, to be increased to £80 per annum after five years' service.

WALES.

THE EBBW VALE DISPUTE.

We learn from the *Western Mail* of March 16th that the dispute between the directors of the Ebbw Vale Workmen's Fund and the medical men employed under the fund entered on a new stage on March 15th. The various phases of the dispute need not be related here. Those of our readers who are interested in the matter have had abundant opportunities of following the sequence of events. It need only be recalled that when the medical men formerly employed under the fund were replaced by practitioners not members of the British Medical Association, a large number of workmen in the Cwm and Waunllwyd district, owing to their confidence in Dr. John Sullivan, one of the dismissed doctors, gave notice to the Ebbw Vale Company to desist from making any more deductions from their wages towards the Ebbw Vale workmen's doctor's fund, and Judge Owen ordered that the contributions during a period of six months should be refunded. This award placed the fund in serious financial difficulty. The liability altogether amounted to over £1,000. Mr. F. Mills was asked to intervene, and the following provisional agreement was proposed:

That, in view of the contents of Mr. Mills's letter of the 24th ult., wherein it was stated that Dr. Sullivan had decided to waive all claims that he might have against the doctor's fund entirely, in the interests of peace, the judge's award of £196 3s. 1d. in recent county court actions be dropped entirely. Further, that in settlement of the whole dispute, the fund section offered, and the Cwm section decided to accept, the sum of £150, being the estimated total of the present liabilities of the Cwm section. The whole of the above agreement is subject to the appointment of Dr. Sullivan.

This agreement was at first rejected, but after further negotiations, and after an independent ballot had been taken of the whole of the workmen of the Ebbw Vale and district, it was accepted by a majority of 252. We reserve comment on the matter till we are in possession of full information. In the meantime we wish it to be understood that the facts stated above are taken from the *Western Mail*, with which lies the responsibility for the accuracy of the statements.

SCHOOLS MEDICAL WORK AT BARRY.

At a special meeting of the Barry Education Committee held on March 8th, the head teachers of the various schools attended and discussed the proposals of the school medical inspector (Dr. W. Lloyd Edwards) to minimize the clerical work imposed upon head and assistant teachers in carrying out the new regulations. With a few alterations, the scheme adopted provisionally by the committee included the appointment of a school nurse (not necessarily a trained nurse) to assist the school medical officer at the medical inspection, in doing clerical work, such as entering details on cards, etc., the nurse to attend the schools in accordance with a time-table. Certain preliminary work, however, would still remain for the teachers to do; the resolution requiring the teachers to test the children's vision annually was rescinded, but the teachers agreed to report particularly bad cases to the school medical officer.

GOVERNMENT GRANTS TO EDUCATIONAL INSTITUTIONS.

The Civil Service Estimates just issued provide for an additional grant of £15,000 to the Welsh University and constituent colleges. The grant of £20,000 to the University College of North Wales building fund is not repeated this year. The £15,000 is to be apportioned between the

University of Wales and the University Colleges of North and South Wales and Aberystwith. The allocation of the particular amounts to the three colleges and the university will be made later. The estimates also provide for a grant of £4,500 to the National Library of Wales and £2,000 to the National Museum of Wales.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

UNIVERSITY OF EDINBURGH—HISTORY OF MEDICINE.

IN his third lecture, Dr. John D. Comrie dealt with the early Greek philosophers and physicians, health temples, and incubation. Between the fifteenth and fifth centuries B.C. Asiatic influence had gradually increased in Greece. Within this period the people seem to have lived with a richness to which Latin poets looked back in longing as the "age of gold," and they seem to have dwelt in well-built cities possessed of efficient storage and drainage systems. To this period Aesculapius belongs. His origin is shrouded in obscurity. Homer makes him a chieftain from Trikke in Thessaly instructed in the knowledge of healing herbs by Cheiron the Centaur on Mount Pelion. Homer gives him two sons who fought before the walls of Troy, both of whom were warriors first and then healers. Apollo was the reputed father of Aesculapius, and a goat his foster-mother. The cult of Aesculapius originated in Epidaurus. In early Greece physicians were not very clearly separable from philosophers. The latter took for their province the whole sum of human knowledge. Pythagoras (about 580 B.C.) was one of the earliest of these. He believed in the doctrine of transmigration, enjoined a rigid dietary, with abstinence from flesh, and forbade certain vegetables, especially beans. He valued music in the treatment of diseases, particularly in disorders of springtime and in affections of the mind. He introduced oxymel of squills from Egypt into Greece, and he strongly recommended onions, and exercise in the gymnasium. The earliest physician of whom there is any considerable record was a fellow-townsmen of Pythagoras, by name Democedes (born about 540 B.C.). His history is given by Herodotus (Book iii, 130 ff.). From this it would appear that the remuneration of the physician consisted chiefly of gifts, and that the various cities had public medical officers. He left his country and attached himself to Polycrates, who paid him two talents (£487 10s.) for his services. Then he went to Samos. Chiefly to him was due the high reputation of the physicians of Crotona. Democedes successfully treated Darius for a bad sprain of the foot, where the Egyptian physicians had failed. He cured the wife of Darius (Atossa, the daughter of Cyrus) of an abscess in the breast, and thus gained his freedom from slavery. Among the early philosophers who concerned themselves with medical subjects should be mentioned Alkmaeon of Crotona, a follower of Pythagoras, who dissected the eye and originated the theory that the brain is the seat of the soul. Also Empedocles of Agrigento (495-435 B.C.), who suggested the principle of evolution on which Darwin based his theory. Anaxagoras of Klazomanae, who announced views on sleep and breathing, and held that the chief acute diseases were due to the deposit of bile in the lungs, vessels, pleura, etc., deserves mention. A certain Ctesias, who had probably been a physician in the Greek army of Cyrus, and was taken prisoner at the battle of Cunaxa (407 B.C.), treated the wounds of Artaxerxes, King of Persia, and subsequently visited India. The question of how far Greek medicine was indebted to the medicine of India and how far Indian medicine was indebted to Greece was discussed. Probably Western and Indian medicine developed quite independently, though they derived something from each other in the time of Hippocrates. In his fourth lecture, Dr. Comrie said the famous medical schools of ancient Greece were in Kyrene, Kroton, Sicily, Rhodes, Knidos, and Kos. In some cases, as at Kos, the school sprang up near a temple of Asklepios, but general medicine was a branch of science taught by the philosophers or by the Asklepiad families, who retained their secrets with the greatest care. These ancient Greek physicians derived their surgical knowledge from accidents

in the gymnasiums and from their practice in their almost constant wars. In the Anabasis of Cyrus and Xenophon military surgeons accompanied the troops. Cure by rest, diet, cheerful surroundings, and suggestion was carried out at the numerous Health Temples throughout Magna Graecia. Epidaurus was the best known of these. Its theatre was capable of holding 12,000 persons, and outside the temple precinct was the Stadium capable of holding 20,000 spectators. Thus pleasure helped the return to health. There were sacred wells and baths and lying-in rooms near. Sophocles was in his youth a priest at Epidaurus. Incubation was practised. Various cures were described.

WESTERN INFIRMARY APPOINTMENT.

THE managers of the Western Infirmary have filled up the vacancy created by the death of Dr. Lindsay Steven by promoting Dr. Wm. MacLennan to be a visiting physician. Dr. MacLennan has served only a few years as assistant physician, but for the past year has been continuously acting in charge of wards, first as substitute for the late Sir Thomas McCall Anderson, and since his death he continued to take charge of the same wards during the prolonged interregnum consequent upon the proposal to transfer the clinical chairs to the Royal Infirmary. During these months Dr. MacLennan has proved a popular and successful teacher. His claims for promotion were felt to be so strong that the managers appointed him to the full physicianship without throwing the post open to competition.

RUCHILL FEVER HOSPITAL.

THERE seems to have been renewed friction at Ruchill Fever Hospital between the matron and the physician-superintendent. The first public indication of trouble was a recommendation by the Hospital's Committee that the physician-superintendents at Belvidere and Ruchill should change places, Dr. Johnstone going to Belvidere and Dr. Brownlee in exchange taking charge of Ruchill. This motion was adopted by a full meeting of the town council, but no discussion was permitted of the reasons which had led to such a step. Since then one of the town councillors has made a long communication to the press which indicates that there was serious friction between the matron and the superintendent. As the statements of the other side have not been published yet, it would be inexpedient to offer any comments, but some of the matron's entries in the logbook are couched in extremely autocratic and peremptory terms, which certainly did not make for peace

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

THE GENERAL ANAESTHETICS BILL.

WE have received from the Honorary Secretary of the Incorporated Dental Hospital of Ireland a copy of the following resolutions adopted at a meeting of the staff held recently in Dublin.

First Resolution.

THAT the members of the staff of the Incorporated Dental Hospital of Ireland, having had under consideration the General Anaesthetics Bill, 1908, as submitted by the Privy Council to the General Medical Council, do approve the general principles of the bill, but are of opinion that the clauses relating to registered dentists should be modified. They would respectfully point out that dental students, before they present themselves for their final examination, are required to produce evidence of having received instruction in general medicine, surgery, and physiology, as well as in the administration of anaesthetics; they are consequently of opinion that if the course of instruction in the latter subject were made identical for medical and dental students, the same privileges could with perfect propriety be extended to dentists as are given to medical men by Clause I of the bill.

In order to give effect to these proposals they would suggest the following amendments to the bill.

1. That Clause I should read as follows:

That any person other than a legally-qualified medical practitioner registered under the Medical Acts, or legally-qualified dental practitioner registered under the Dentists Act, 1878, who shall wilfully administer or cause to be administered to any other person, by inhalation or otherwise, any drug or substance, whether solid, liquid, vaporous, or gaseous, and whether pure or mixed with any other drug or

substance, with the object of producing a state of unconsciousness during any medical or surgical or dental operation, act, or procedure or during child-birth, shall be liable on conviction before a court of summary jurisdiction for such offence to a penalty not exceeding ten pounds, and in the case of a second or subsequent conviction to a penalty not exceeding twenty pounds, provided always that a person shall not be liable to a penalty under this section if in conducting such administration he was acting under the immediate direction and supervision of a legally-qualified medical or dental practitioner, or if the circumstances attending the administration were such that he had reasonable grounds for believing, and did believe, that the delay which would have arisen in obtaining a legally-qualified medical or dental practitioner would have endangered life.

2. That Clause 2 be amended as follows:

All licensing bodies in the United Kingdom recognized by the General Council of Medical Education and Registration of the United Kingdom shall require that all candidates, both medical and dental, before presenting themselves for their final examinations, shall have received thorough theoretical and practical instruction in anaesthetics, and shall have personally administered anaesthetics, under the supervision and to the complete satisfaction of their respective teachers.

3. That Clause 3 be deleted.

Second Resolution.

That no legislation which does not deal with local anaesthetics will adequately meet the mischief against which the General Anaesthetics Bill is aimed.

We are informed that the hospital staff comprises twenty dentists, of whom eight hold additional medical qualifications, and eleven medical men who are anaesthetists.

SANITATION IN NATIONAL SCHOOLS.

Mr. Kelly, Senior Inspector of the Board of National Education in Ireland, has again drawn attention to the deficient sanitation in national schools. In Belfast, he said, much had been done to improve the condition, but much still remained to be done. The accommodation, which should be 10 sq. ft. for each pupil, was insufficient in 27.7 per cent. of the schools. One school had floor space for 232 pupils, but 331 were present; in another there was accommodation for 18, while 39 were present. In eight schools the ventilation was deficient. During the epidemic of cerebro-spinal fever much more attention had been paid to sanitation by the authorities than would have been given if the epidemic had not occurred. Worse reports come from other parts of Ireland, and it is evident that a radical change is necessary in the control of the sanitation of elementary schools.

LISBURN SEWERAGE SCHEME: COMPLETION OF WORKS.

For some years past a new sewerage scheme for Lisburn has been under construction, and on March 12th the Urban District Council paid a formal visit of inspection, and found the working most satisfactory. The scheme allows for 50 per cent. increase of population. The rain-water from the street is collected into the old sewers, and led direct to the river or the by-wash; that from the roofs into the new, along with the sewage of the town. At the purification works the sewage is passed through two grit or detritus chambers, then through two settlement tanks having a capacity of 375,000 gallons, where the major part of the organic suspended matters are left; these solids are submitted to a septic action by which they are liquefied; the liquid is then passed into one or other of a series of ten contact bacteria beds, which are automatically filled and emptied once in the twenty-four hours. The purified liquid from the contact beds is automatically discharged on to the area of land in possession of the council. These works are considered among the best, if not the best, in the kingdom, and have been carried out very economically at a cost of £54,000, or about £3 a head of population, payable in sixty years. At a luncheon subsequent to the inspection much credit was given to the engineer in charge, and to Dr. St. George and all others who had brought the work to such a successful issue.

UNSATISFACTORY VACCINATION IN BELFAST.

At the meeting of the board of guardians on March 9th, a letter was read from the Local Government Board intimating that vaccination was not in a satisfactory condition in the union. In 1907, 4,269 defaulters were reported, and of this number 3,044 were returned by the vaccination officer as vaccinated. In 1908, 4,308 defaulters were returned, and up to February 10th, 1909, only 1,035 had been returned as vaccinated; the last figure referred

only to certain quarters of the year and certain districts. The medical officers state that many parents do not allow the proper number of marks and the child is removed, and subsequently inefficiently vaccinated. The result is that in many cases the protection against small-pox is not what it should be.

Correspondence.

SLEEP AND WANT OF SLEEP.

SIR.—The very interesting paper of Dr. Farquharson on sleep and want of sleep, which appeared on February 27th, has not provoked any immediate reply, such as it was intended to produce, from some up-to-date physiologist or pathologist. I am writing chiefly to emphasize his request for enlightenment. Of the numerous interesting practical points which he brings out, almost all are within my own experience or observation. The double action of tea is certain and important. I myself am usually put to sleep at once by a cup of warm if not too strong tea; whereas a cup of strong tea taken several hours before bedtime ensures me a bad night. With Dr. Farquharson, I suppose that in the former case the hot water has something to do with the result. People who habitually drink tea are kept awake by coffee, and vice versa. The hot (but not extremely hot) whole-bath or foot-bath seems to act in accordance with Durham's principle. Of hypnotics, I suppose paraldehyde would be among the best, but for its horrible taste. Urethane is little used now; but I have found it safe, agreeable, and moderately effectual. Sulphonal is good, and veronal better, though their comparative insolubility is troublesome. I see a soluble form of veronal advertised.—I am, etc.

JOHN BEDDOE, M.D., F.R.S., etc.

Bradford-on-Avon, March 10th.

THE PREVENTION OF DEATHS BY BURNING IN CHILDREN.

SIR,—There are in this country 1,400 deaths annually from burns and scalds in children under 5 years of age. The great majority of these deaths are, with a few simple precautions, absolutely preventable, and it is to this fact that I am anxious to call attention. Think of it—all these hundreds of babies lost unnecessarily each year; think not only of the dreadful waste of infant life, but also of the awful pain and agony of this terrible ending. In addition to those who lose their lives there are an enormous number who are injured in varying degrees, so that the sum total of suffering is appalling. The Legislature has recognized that some action was necessary, and a beginning has been made by Clause 15 of the new Children's Act, which comes into force on April 1st, and which enacts that—

If any person over the age of 16 years who has the custody, charge, or care of any child under the age of 7 years, allows that child to be in any room containing an open fire grate not sufficiently protected to guard against the risk of the child being burnt or scalded, without taking reasonable precautions against that risk, and by reason thereof the child is killed or suffers serious injury, he shall on summary conviction, be liable to a fine not exceeding £10.

The two most important contributory causes of this very large number of deaths and accidents from burning are (1) the wearing of inflammable garments, and (2) the absence of efficient fireguards.

The chief material used by the poor for the undergarments of children is flannelette. It has the great advantage of being warm and cheap, and the great disadvantage of being very inflammable. But there is no substitute for it within reach of the purse of the poor. I have made many inquiries amongst those who should know, and not one of them could suggest any fabric which could be used in its place. Those materials which will only burn with great difficulty, for example, good flannel, are much too expensive. The varieties of flannelette which are said to be non-inflammable are not really so. I have procured a very large number of samples of flannelette from drapers in the town, of all prices, ranging from 2½d. to 10½d. per yard, many of them declared to be non-inflammable, and with the single exception of one, to which I refer below, they all flamed on the application of a match, the dear ones almost, if

not quite, as readily as the cheap. The one exception is a patent material much advertised, especially by coroners, which certainly burns with great difficulty before washing, but which catches fire almost as readily as ordinary flannelette after repeated washing, and as the cheapest variety of this costs 6½d. per yard we can hardly expect the poor to pay this price instead of 2½d. or 3½d. for advantages which are so transient. The prevention of these deaths does not depend on the abolition of flannelette garments; this is a quite impracticable suggestion.

On examining the second cause, want of proper fireguards, I am much more hopeful. This fact was present in 85 per cent. of 1,600 inquests held on children dying from burns. The difficulty of getting the poorer classes to use these guards is, of course, their cost. It is the bounden duty of all district visitors, nurses, and others who come in contact with the poor to impress upon them on every possible occasion the great danger which their children run by being left in rooms with unprotected fires. But the best method of prevention that I can suggest is that an addition should be made to the building by-laws of every council rendering it compulsory to fix efficient fireguards to every grate in any new building under a rental value, say, of £26 per annum, erected in the town. I fix a rental value of about £26 because it would not be necessary to compel the fixation of guards in the better class of houses. This is already done voluntarily by the parents in almost all cases where there are children, and in addition they usually have nurses to look after them. As a matter of experience, it is practically always among the poor, where the parents cannot leave any one in charge, that the deaths from burning in children occur.

This by-law would add practically nothing to the cost of a house. I have consulted two expert practical builders in the town, and they tell me that the additional expense for a house costing £350 would be about 30s. to 35s., that is, less than ½ per cent.

My proposal is not merely an academic expression of an ideal. It is well within the function of a municipal council to do this, and I have ventured to write and suggest such an addition to the building by-laws to the Works Committee both of the Brighton and Hove corporations, with what result I cannot as yet say, but I trust they will see their way to adopt my suggestion, and so save many children from a dreadful death, and many more from pain and suffering.—I am, etc.,

Hove, March 9th.

L. A. PARRY, M.D., B.S., F.R.C.S.

COLLIERY ACCIDENT STATIONS.

SIR,—In the JOURNAL of February 27th the opening of a colliery accident station at Benwell Colliery, Newcastle-on-Tyne, is reported. I should like briefly to emphasize the necessity for such stations becoming universal at all pit-heads.

Over six years ago, on my initiative as surgeon to the colliery, and with the cordial co-operation of the management, such a station was opened at the Bowhill Colliery, Cardenden, Fife. Nothing elaborate was attempted. A large room was erected with tables on which stretchers could be laid; a hot and cold water supply was laid on, with electric hand-lamps, and cupboards for storing splints, antiseptics, and dressings. Opening off this room was the shed in which the ambulance wagon and the wheeled litter were kept, so that the patient after receiving first-aid treatment was under cover until removed to home or hospital as the case might be. The ambulance room was a useful centre for the meetings of the ambulance corps, and that it made for efficiency was shown by the fact that a team of pit head men in one year gained the Fife miners' ambulance cup, the Dunfermline Matheson cup, the Dundee silver challenge shield, and was second for the President of the St. Andrew's Ambulance Association's cup at Glasgow—as good a record, I should imagine, as any bona-fide working man's team ever had.

Failing a room of this sort, the patient has to be taken to an engine-room or similar place at a temperature of 65° to 75° F., with the inevitable discomforts of smell and noise.

Such stations should not fall to be provided by private philanthropy, but should be secured by legislative enactment. They are a necessity at every pit-head.—I am, etc.,

DAVID RORIE, M.D. Edin.

Culls, Aberdeenshire, March 15th.

OPHTHALMIC SURGEONS AND SPECTACLE VENDORS.

SIR,—In the JOURNAL of March 13th, p. 693, attention is drawn once again, by "Specialist," to the notorious amount of unqualified practice in eye refraction work. In addition to the optologist, pure and simple, the prescribing chemist has now added "sight-testing free" to his attractions.

I know of one optologist who from selling spectacles has taken to making them, and has, I believe, made himself competent to correct and estimate errors of refraction. If only he were allowed to paralyse accommodation when necessary I believe his results would be correct. Although he acts on his own, he has been taken under the wing of a qualified man who figures in the directory as consulting ophthalmic surgeon to the local infirmary. No doubt when nurses use ergot or administer chloroform he will use atropine, and forthwith blossom forth as a competent rival to his coadjutor in the department of refraction work.

To anyone who considers this matter from an outsider's point of view it is plain that it is the "free" test which draws. Many patients can ill afford guinea fees and yet would not of their own accord go to hospital if their own doctor would deal with them at, say, a half-guinea fee. Instead of doing so he sends them to the eye hospital or to the optologist if they declare their inability to afford the usual consultant's fees. If at the eye hospital they are handed over to a nurse they probably prefer the sumptuous room of the optologist, who, in spite of the free test, seems to be able to make a good profit out of the glasses he prescribes and sells to them. It really almost seems as if the profession were the culprit to a large extent, and especially the general practitioner.

Seeing that refraction work has to deal in most cases with a deformity rather than a disease of the eye, one does not quite see why the general practitioner should not make himself competent—at least, as competent as the optologist—to take many of these cases in hand. Certain cases, as in other departments of his work, he could send to a specialist. Must he send every case of displacement that requires a pessary to a gynaecologist? The general practitioner could afford to do the work at a half-guinea fee, and that without depriving the ophthalmic specialist of anything. Of course, if the rising young specialist is prepared to do such work at such a fee, the general practitioner would probably prefer to send the cases to him, and a little explanation would probably convince patients of the wisdom of going to him.

Governments in this free country are so apathetic, where only life or limb are concerned, about protecting citizens against themselves or their deceivers, that it is hardly likely the optologist will be restrained. He is more likely to be recognized as a benefactor of the people.

It rests, then, with the profession, both in its own interests and in those of the public, to checkmate unqualified practice, and I believe the general practitioner could, if he cared, successfully do this in this particular matter.—I am, etc.,

March 15th.

"G. P."

SIR,—I am very pleased to see the letter by "Specialist," as matters have now reached a point when something should be done. Not very long ago a well-known eye specialist used to see patients at a cutler's shop. A sight-testing optician advertises in the local papers that he works "in co-operation" with a well-known local and London oculist. Moreover, in several districts eye hospitals have appeared which are nothing more or less than an illicit method of advertisement.

Surely taking a house and putting in very large type "Eye Hospital" in front of it does not transform it into a hospital. Recently such institutions have issued reports and published the names of the members of the committee, but there appear no subscribers' list or list of donors, etc., nor are the accounts audited by a chartered accountant. Some of these reports are distinctly amusing and not unfamiliar to some of your readers.—I am, etc.,

March 15th.

ANOTHER SPECIALIST.

THE DIAGNOSTIC VALUE OF HUNGER PAIN.

SIR,—In a number of able and interesting articles on the diagnosis and treatment of ulcer of the stomach and duodenum by surgical writers, published in the BRITISH

MEDICAL JOURNAL during the course of the last few months, I notice that it is apt to be assumed that the presence of "hunger pain" is a sign pointing conclusively to the presence of duodenal ulcer. Now I believe this to be an error, for the following reason. The natural history of a case of duodenal ulcer is usually as follows: In early manhood the patient—for he is usually a male—begins to suffer from recurring attacks of dyspepsia characterized by pain in the later period of digestion when the stomach is getting empty (hunger pain). This is the stage of hyperchlorhydria. In the great majority of instances the case does not go further than this, but the attacks gradually cease, and all is well. In a few, however, the attacks of pain become more frequent, and finally almost constant. This is the stage of continuous hypersecretion. Even this may be recovered from with proper treatment, but in a certain number unmistakable signs of duodenal ulcer appear, and the case passes into the hands of a surgeon. The latter then seems to argue thus: "I find in this patient a duodenal ulcer: he gives a history of hunger pain, therefore the presence of hunger pain is always indicative of duodenal ulcer." The fallacy of this method of reasoning does not need to be insisted upon, but is perhaps not surprising in the mouth of one who does not have opportunity of seeing these cases in the early, or functional, stage, for the fact is, I believe, that the formation of a duodenal ulcer is usually only the terminal event in a case of hypersthenic dyspepsia, and the hunger pain is a sign, not of the ulcer, but of the over-production of hydrochloric acid which almost invariably accompanies it.

I know that Mr. Moynihan, for instance, deals rather contemptuously with this view, for in an article which appeared in your issue for November 28th last, he writes:

It is a very curious feature in connexion with this disease [that is, duodenal ulcer] that perfectly accurate accounts of its symptomatology are given by authors who do not seem to have the remotest conception that the condition they are describing is not, as they suppose, one of "functional" disorder, but one in which a demonstrable organic lesion is present. The vague terms, "hyperchlorhydria," "acid dyspepsia," "nervous dyspepsia," are given very generally as diagnoses; they are too often words without meaning, clinical synonyms for the pathological condition duodenal ulcer.

I feel sure, however, that all experienced practitioners will agree with me that in saying this he goes too far, and that functional hyperchlorhydria has a real existence and is infinitely commoner than duodenal ulcer, and that to advise operation in all patients who exhibit hunger pain would be to exaggerate the domain of operative surgery and would only tend to bring discredit on the surgical treatment of gastric disorders, to which we owe so much and to which Mr. Moynihan himself has made such valuable contributions.

I should not have troubled you with this letter, Sir, were it not that I feel, and no doubt many feel with me, that the time has come to reassert emphatically the conservative view that the great majority of cases of dyspepsia met with in practice are due to functional disorder and not to organic disease, and although for the purpose of this protest I have dealt with only one well-defined symptom it would have been easy, had space permitted, to have selected, from the writings of surgeons, others, the significance of which is just as much and as commonly exaggerated.—I am, etc.,

London, W., March 16th.

ROBERT HUTCHISON.

THE COLD-BATH TREATMENT OF TYPHOID.

SIR,—I do not know whether Dr. Manasseh in his letter of February 27th quite sees my point. Since epidemics of typhoid vary so much, the experience of single observers must be fallacious. All who have tried it agree that cold sponging is helpful and relieves many symptoms, but does it really reduce the average death-rate by anything like 7 per cent., as the Brand baths do? This can only be proved by extensive statistics gathered in many places and during outbreaks of varied virulence.

Few things seem better attested in modern medical history than the lowering of typhoid mortality where the bath system was employed in its essentials, but the validity of the proof depended on the great numbers of cases in different places and at different times which yielded the same results. Thus, at Brisbane before the baths were used the deaths amounted to 14.8 per cent. in

1,828 patients; afterwards there were only 7.5 per cent. in 1,902. Drasche in Vienna found his rate fell from 16.2 to 9.3. Osler reported that from 6 to 8 per cent. more lives were saved. In the Prussian army the rate fell from 25 to 8 per cent. Wilson and Salinger had a death-rate of only 7.5 in 1,903 patients thus treated. In short, many thousands of cases showed a mortality less by about 7 per cent. than that of others who were treated just the same except for baths.

I want to see similar statistics for cold sponging and packs. If the seven lives in each hundred are saved by this method, let us by all means adopt it as far easier and simpler. If not, what is the active agent in the bath system which saves life; how can it be applied in a less impracticable way? If the great hospitals where typhoid is treated would give statistics of mortality under cold sponging on a large scale, it would be possible to see where the life-saving element of baths comes in, whether it be the longer continued abstraction of heat or what else. Dr. McCrae, in Osler and McCrae's *System*, vol. i, p. 213, speaking of these substitutes for baths, says:

They have no marked influence on the general condition, and while they give comfort and are undoubtedly helpful, their effect is in no way to be compared to that which follows hydropathy in the form of baths.

He adds that we are unable to explain this, but that it is clear that baths have a marked effect on the course of the disease, and prevent many complications, and finally that the mortality is less than under any other system. He suggests, indeed, that baths cause a greatly-increased excretion of toxins, besides aiding the circulation and nervous system, and points out definitely that the reduction of temperature is not the main object of the baths.

If these are the views of one party, is there any means of testing them by a collective investigation committee; and, if they are true, what valid substitute for baths can be recommended for use in private and military hospitals in the field, where labour and time are wanting? The question is surely worth testing, since it involves a mortality of 7 per cent. in such large numbers of patients.—I am, etc.,

Clifton, Bristol, March 2nd.

G. PARKER.

THE REMEDIAL USE OF ALCOHOL.

SIR,—I have read with much interest the most excellent address on the above subject by Dr. James Macdonald, also Dr. Hill's letter of February 1st. Dr. Hill agrees that an ounce of practice is worth a pound of theory. Certainly Dr. Hill has not had much more than the ounce of practice, for 40 to 50 cases are very few to generalize on, and a great many medical men attend a larger number of cases of lobar pneumonia in twelve months. Dr. Hill surely has not read Dr. Macdonald's address very carefully.

The medical staff [that is, of the London Temperance Hospital] claim that the results they obtain without alcohol compare favourably with those of other hospitals. Whether that be so or not, the unwisdom of forming a broad generalization from a comparatively limited number of cases is obvious. And, besides, in a disease like pneumonia there are many contributory factors and side elements which have to be taken into consideration.

In spite of this, Dr. Hill mentions his 40 to 50 cases of pneumonia, and presumably generalizes from them. Is Dr. Hill quite certain that no alcohol was administered in any of his cases? It is not very clear what clay soil has to do with the mortality of pneumonia, unless it is that cases of pneumonia do better when the atmosphere is damp; some authorities, I believe, consider pneumonia more fatal when a cold dry east or north-east wind prevails.

It is difficult to comprehend what Dr. Hill means by "paralysing effect on the cardiac nerves." Does he mean that the cardiac muscle is paralysed by the action of alcohol on some nerves connected with the heart? and, if so, which nerves—the cardio-inhibitory fibres of the vagi or the cardiac fibres of the sympathetic, or perhaps the ganglia (and the nerve fibres proceeding from them) in the walls of the heart itself? Dr. Hill writes as if the innervation of the heart and the actions of drugs acting on it, either directly or indirectly, were fully understood.

We will take a case of lobar pneumonia with "over-distension of the right side of the heart, with the small, rapid, feeble, and irregular pulse, the embarrassed

breathing, the facial pallor, and the other symptoms of what has aptly been described as right heart misery: "alcohol is administered and dilatation of superficial blood vessels follows "through the influence of the drug on the vasomotor nerves. In this way the action of the heart is relieved and its efficiency is increased"; the left ventricle is able to contract more fully (because of less peripheral resistance), the left auricle then empties itself more easily, and this in its turn, working back through the lungs, relieves the right ventricle and auricle, and thus lessens the risk of cardiac failure.

There is also the "sedative, numbing action of which the physician makes use," extremely important in lobar pneumonia. Dr. Hill does not tell us how he procures "absolute rest"; perhaps he has also been lucky in having no delirious patients among his 40 to 50 cases of lobar pneumonia as in having no deaths.

Again, there is the disputed stimulating action of alcohol on the cardiac muscle itself, not a "paralysing effect on the cardiac nerves." Also "the widely-admitted fact that alcohol possesses a certain definite value as a food," and "is readily absorbed by the stomach when other nutriment cannot be retained," etc.

The last two paragraphs in Dr. Hill's letter are rather astounding. What could be more dogmatic than "... and the cause of the cardiac failure in 99 cases out of 100 is—alcohol"? It is a pity that Dr. Hill did not read through Dr. Macdonald's address more carefully before generalizing from his 40 to 50 cases.—I am, etc.,

L. C. V. HARDWICKE, M.B.

Assistant Medical Superintendent, Paddington Infirmary, W.

PIGMENT DISAPPEARANCES IN SKIN AND HAIR.

SIR,—In the *EPITOME in the BRITISH MEDICAL JOURNAL* of February 27th is a review of observations made by Schein upon "pigment disappearances in skin and hair." With his observations I do not agree.

He says that long hairs whiten before short ones, highly pigmented hairs do the same earlier than those of lighter shades, and that hairs whose follicles have produced hairs for longest periods whiten earliest. In the *BRITISH MEDICAL JOURNAL* of July 4th, 1908, I pointed out that the hair of the beard whitens in the whole of the mental nerve areas before any other part of the beard follows suit; and that sometimes the hair of the beard in the skin of the cervical nerve supply whitens before the mental nerve areas, a very distinct line of demarcation marking the delimitation.

The mental nerve area contains long hairs, short hairs, and hairs of various ages and pigmentary shades; in fact, there is a greater variety of all these kinds of hairs here than in any other region of the beard, and yet they all whiten before longer and more highly pigmented hairs elsewhere in the beard. This could not be so were Schein's observations correct. I also pointed out that some of the shortest as well as the longest hairs of the chin whiten before other parts of the mental nerve areas, and those particular hairs grow in that part of the skin at which the mental nerves become cutaneous.

My criticism of Schein's observations comes to this: that even in the limited state of our knowledge concerning pigmentation, a conception of the appearance or disappearance of pigment is imperfect unless it include the influence of the nervous system.—I am, etc.,

London, W., March 10th.

G. LENTHAL CREATLE.

APPENDICITIS AND RHEUMATISM.

SIR,—In connexion with the question of rheumatic appendicitis recently raised by Dr. Eustace Smith I think the following case very suggestive:

A lady, aged 40, for the last year has at every menstrual period had some manifestation of rheumatism, generally taking the form of a swollen and painful joint. In August, 1908, she had what appeared to be a definite and typical attack of appendicitis, though, as it occurred at the time of a period, there was a doubt whether it might be due to ovarian trouble. A few weeks ago, again at the time of a period, the patient had a second attack, which began with vomiting, fever (102°), and general abdominal pain and tenderness, which after a few hours settled down to the right iliac region, with its maximum intensity over

the appendix. Associated with this were painful joints, severe intercostal rheumatism, and a stiff neck. This led to my trying sodium salicylate, with the result that the appendicular symptoms, though they had promised to be more severe than in the first attack, cleared up with remarkable rapidity.

The question of rheumatic appendicitis seems to me of considerable practical importance, for, as far as my experience goes, sodium salicylate is not often given for appendicitis; indeed, in these cases the modern physician is for the most part content with watching for the right moment at which to call in his surgical colleague. Provided he does not allow its use to drug his vigilance, he might, perhaps, with benefit in the future more often combine sodium salicylate with his watching.—I am, etc.,
Shanklin, I.W. J. A. B. HAMMOND.

DISEASES MODIFIED BY CLIMATE.

SIR.—Your reviewer of Dr. Stoddart's book on Psychology, in the *JOURNAL* of March 6th, quotes the passage as to the rarity of general paralysis of the insane following syphilis in the East—India, China, Japan, etc.—when compared with European countries, and though not actually doubting this, seems at a loss for an explanation.

I have no doubt as to the accuracy of the observation, and have long held the following as the reason: In hot climes, the skin being more active is more liable to disease, just as kidney troubles are more frequent in colder zones, these two systems being complementary to a certain extent.

The virus of syphilis has a special affinity for the epiblast from which both the nervous system and the skin are developed, and it is notorious that when this disease is accompanied by a good skin rash, the victim is much less likely to suffer from locomotor ataxy or general paralysis of the insane in the future. This is exactly what happens in the East, on account of the greater susceptibility of the skin to disease, and the nerve centres escape.

The conditions and strain of life are of less moment in the East, whereas the struggle for existence in the West, being more acute, might be a factor in making the nervous system more prone to the disease. Of course this only applies to natives, and not to Colonials.—I am, etc.,

THOMAS JOHNSTONE, M.D., M.R.C.P.

Leeds, March 15th.

RURAL NURSING ASSOCIATIONS.

SIR,—In the *BRITISH MEDICAL JOURNAL* of March 13th, p. 694, Dr. Wm. Milligan calls attention to rural nursing associations. The Midwives Act has so frightened the women in country villages, not one of them dare help their sisters in distress. The excellent women, who were wonderfully clean, kind, and motherly, who would stay for nights and days with a woman in labour, nursing her, feeding her, and looking after the wants of the husband and his children, are now warned, threatened, and replaced by young unmarried nurses whose questionable knowledge of the efficient use of antiseptics and cleanliness is counterbalanced by their lack of motherly experience and the art of feeding and managing a baby. Alas! the splendid spirit among village women to help one another is being crushed out by this Midwives Act.

Dr. Milligan has in no way exaggerated the situation, for practically all that he has said applies to my district; the nurse is often driven upon her rounds from village to village in a smart dogcart, she visits every possible case, making friendly calls of inquiry, diagnosing and treating whatever case she may be called in to, and my patients are attended by her frequently without my knowledge and directions. The committee of ladies are anxious to make both ends meet, and touting for patients to pay subscriptions to the association is keen. One of the ladies once accidentally told me that "her nurse was as good as any doctor." I have been threatened with all sorts of penalties and disgrace if I do not rush off to the help of this nurse whenever summoned; but as she practises medicine and minor surgery, it is a question whether I may not render myself answerable to the General Medical Council for covering an unqualified practitioner.

The Midwives Act has introduced a class of practitioners who are proving disastrous to the public health and to the qualified medical practitioner.—I am, etc.,

March 15th.

PARISH DOCTOR.

THE MENTALLY DEFECTIVE IN PRISON.

SIR,—In the issue of the BRITISH MEDICAL JOURNAL of November 14th, 1908, Dr. Champneys replies to my letter on the above subject, which appeared in the number of October 17th.

Dr. Champneys takes exception to my having denied more than he asserted. If I erred in that respect, I ask him to accept my apology; but I was not aware that I had denied anything. I made statements which I will now substantiate. Dr. Champneys declines to accept my statements, but whether he objects to them *en bloc* or only in part does not appear. I observe that Dr. Champneys does not bring forward one title of evidence in refutation of my assertions. He does not even state whence he derived the "facts authoritatively published" that more than ever confirm him in his opinion. He quotes an opinion of the Duke of Wellington, but even the Duke had his limitations, and the opinion of a person, however eminent, on a subject he has had no experience of must be largely discounted.

With your permission, I will quote some figures from the Official New Zealand Year Book for 1908 in support of the statements made in my former letter. I stated:

I. "That from being, perhaps, the most drunken, New Zealand had become one of the most sober countries inhabited by the English-speaking race." I will quote the amount of alcoholic liquor consumed by the people of New Zealand (excluding Maories), the other Australasian colonies, and the United Kingdom:

Consumption of Spirits, Wine, and Beer per head of the Population for the Years 1901-6 (p. 293, Official New Zealand Year Book, 1908).

	Spirits.	Wine.	Beer.
	Gallons.	Gallons.	Gallons.
New Zealand	0.755	0.144	9.389
New South Wales	0.81	0.57	9.76
Victoria	0.70	0.85	12.04
Queensland	0.82	0.29	10.38
South Australia... ..	0.40	2.53	8.17
Western Australia	1.49	1.08	24.74
Tasmania	0.53	0.17	9.15

The average annual consumption in the United Kingdom, 1901-5, was spirits, 1 gallon per head; beer, 29½ gallons per head; wine, ¾ gallon per head.

It will be observed that our drink bill is lower than in any of the places mentioned with the exception of Tasmania and perhaps South Australia. The latter colony consumes much more wine but less beer and spirits. The wine is chiefly light and of local manufacture, so it is probable that the South Australians consume less alcohol than we do in New Zealand. Again, on page 232 I find further testimony of the sobriety of the Maorilanders proper:

Among the New Zealand population of European descent there is evidence of less drunkenness than among people who have come from abroad. At the census of 1906, out of a total population of New Zealand over 15 years of age, 55.75 per cent. were found to have been born here; while the proportion of convictions for drunkenness of New Zealand-born Europeans to the total convictions was in the year 1906 about 20 only.

II. "That crime, especially of a serious nature, had decreased under our system of education, the decrease being most marked amongst those who had been educated in our State schools." On pages 237 and 238:

The New Zealand-born formed at the last census 68 per cent. of the whole population; they contributed only 33 per cent. of the prisoners received in gaol. Of the New Zealand population, however, a large number are under 15 years of age, a period of life at which there are very few prisoners; and therefore another comparison is necessary. It is found that New Zealand-born over 15 years of age formed 56 per cent. of the total population above that age; but, as before stated, New Zealanders constituted only 33 per cent. of the total number received in gaols.

I will here remark that if the adult population who had passed through our State schools were winnowed out from those brought up in the Colony and educated in some of the other schools, the effects of our education system

would show better results, both as to sobriety and criminality.

III. "That illegitimacy is gratifyingly small."

Average of annual proportion of illegitimate births in every 100 births for ten years ending 1907 in New Zealand, Tasmania, and New South Wales (p. 249): New Zealand, 4.52; Tasmania, 5.65; New South Wales, 7.01.

The proportion of illegitimate births per 1,000 unmarried women, that is, spinsters and widows, at the reproductive ages, covering a period of twenty years, is shown to be:

Year.	Unmarried Women aged 15 to 45 years.	Illegitimate Births.	Illegitimate Birth-rate per 1,000 Unmarried Women.
1886	56,277	662	10.70
1891	68,980	638	9.25
1896	89,722	834	9.30
1901	105,420	937	8.89
1906	116,506	1,132	9.72

I would point out that 1877 was the commencement of our education system, and that it would not have borne much fruit by 1886, and that in the next quinquennial period there was a substantial drop, which has been fairly well maintained. On p. 250 I find, *inter alia*, that the rate in New South Wales for 1905 was 16.24 per 1,000 unmarried women.

Both Tasmania and New South Wales have religious instruction in the State schools, that of the latter being denominational.

I could quote other figures which would all support the truth of my assertions, but I must regard your "scruples."

I regret that I am not able to withdraw my statement—"It is unfortunate that so many persons holding positions that should entitle their opinions to weight, argue on facts as they imagine them to be instead of as they are." It is quite evident that if Dr. Champneys did not imagine his facts he must have accepted them from some one who did.

—I am, etc.,

Hastings, New Zealand, Jan. 1st.

FRED. DE LISLE,

Member British Medical Association.

TREATMENT OF SCHOOL CHILDREN.

SIR,—Although there have been repeated communications, discussions, and suggestions as to the most satisfactory mode of carrying out the necessary treatment of school children found on examination to be defective, the difficulty seems to have been to discover a means to compel parents and custodians to pay attention to the report of the school medical officer.

The Eccles Council has recently had recourse to the Prevention of Cruelty to Children Act, 1904, which does not sufficiently meet the case.

No notice, however, seems to have been taken of the following paragraphs of Clause 12 of the Children's Charter, which, as the Children Act, 1908, comes into force on April 1st next:

12. Punishment for Cruelty to Children and Young Persons.—

(1) If any person over the age of sixteen years, who has the custody, charge, or care of any child or young person, wilfully assaults, ill-treats, neglects, abandons, or exposes such child or young person, or causes or procures such child or young person to be assaulted, ill-treated, neglected, abandoned, or exposed, in a manner likely to cause such child or young person unnecessary suffering or injury to his health (including injury to or loss of sight, or hearing, or limb, or organ of the body, and any mental derangement), that person shall be guilty of a misdemeanour, and shall be liable—

(a) on conviction on indictment, to a fine not exceeding one hundred pounds, or alternatively, or in default of payment of such fine, or in addition thereto, to imprisonment with or without hard labour, for any term not exceeding two years; and

(b) on summary conviction to a fine not exceeding twenty-five pounds, or alternatively, or in default of payment of such fine, or in addition thereto, to imprisonment, with or without hard labour, for any term not exceeding six months;

and for the purposes of this section a parent or other person legally liable to maintain a child or young person shall be deemed to have neglected him in a manner likely to cause injury to his health if he fails to provide adequate food, clothing, medical aid, or lodging for the child or young person, or if, being unable otherwise to provide such food, clothing,

medical aid or lodging, he fails to take steps to procure the same to be provided under the Acts relating to the relief of the poor.

(2) A person may be convicted of an offence under this section, either on indictment or by a court of summary jurisdiction, notwithstanding that actual suffering or injury to health, or the likelihood of such suffering or injury to health, as obviated by the action of another person.

(3) A person may be convicted of an offence under this section, either on indictment or by a court of summary jurisdiction, notwithstanding the death of the child or young person in respect of whom the offence is committed.

(The italics are mine.)

It will be seen that defaulting parents and custodians will receive at an early date most drastic treatment at the hands of the State if they continue to neglect children and young persons committed to their charge. The intention of the Act seems to be, in the first instance, to throw the onus of providing for medical treatment on the parents and custodians and not on the State.

It is also instructive, as bearing on hospital reform and the questionable need to build any but cottage hospitals in the future, to note that by this Act parents and custodians unable to meet, by insurance or otherwise, the just fees of medical practitioners are expected to claim the use of the infirmaries at present under the control of boards of guardians. This procedure will in time compel these buildings, taken over by borough or county councils, to be properly staffed and organized, and once again to take their rightful position in the economy of the State. It is quite time that voluntarily subsidized hospitals ceased, on the one hand, to bear State burdens, and, on the other, to deprive registered medical practitioners of their legitimate livelihood by underselling.—I am, etc.,

London, S.W., March 13th.

E. ROWLAND FOTHERGILL.

A MEDICAL DEGREE FOR LONDON STUDENTS.

SIR,—In fruitless arguments over the quality of various degrees and diplomas I have repeatedly seen statements and implications such as Dr. Mercier makes under the above heading in your last issue. He says:

The substitution of three professional examinations for the two in the present curriculum before the Conjoint examinee can obtain his diploma is a handicap to the London medical student in comparison with the alumni of other universities. The grievance of the London medical student is that for the same expenditure of time, labour, and money for which a provincial student can obtain a university degree, the London student can obtain the Conjoint diplomas only, which, although well known in the profession to represent professional attainments equivalent to a university degree, are not so regarded outside the profession.

I beg to say that the implication he makes here does not apply to the Scottish universities, and if he says it does, he speaks in ignorance, or quite in face of the facts. For the past twenty-five years at least (I speak from personal knowledge, and of Glasgow University specifically) the Scottish universities have demanded four professional examinations from their graduates in place of three (not two, as Dr. Mercier says) required by the English Conjoint Board.

As regards time and labour they are nearly the same in the preliminary scientific subjects and in those of the second examination, save that at the University separate courses of zoology and botany take the place of one in biology, and that there have to be nine months spent at physiology and histology instead of six. In the more strictly professional subjects the University requires six months' systematic materia medica and therapeutics and six months' midwifery instead of three months in each of these subjects. Pathology gets six months' systematic study and three months' practical pathology and bacteriology, as against a combined three months' course required by the Conjoint Board. Diseases of women have three months' study (twenty-five lectures or clinical meetings) instead of a course of twelve meetings. At the University three years' hospital work are obligatory, but only two are required by the Conjoint Board. It may be said that few Conjoint men are satisfied with the minimum course of study, and the same is true of the University graduate. There the men do twice or three times the amount of anatomy obligatory, double the systematic medicine and surgery, and generally they spend four years at the hospitals instead of the three absolutely necessary.

Coming to the quality of the examinations, opinions

very well may, and, indeed, always will, differ; but, taking the fact that from 35 per cent. to 55 per cent. of the candidates are regularly rejected, the standard at the University can be no mean one. This will be granted by the most biased, as, in view of Scottish educational history, he will hardly attribute an essential want of brain to the North. If the course of study required and the examinations of the London University are no obstacle in the way of the Conjoint men, as Dr. Mercier says, then they are in a better position for acquiring a degree than are the Scottish students, inasmuch as their course of study may be pursued at any one or more of a large number of educational institutions, whereas the Scottish University man is compelled to study at least two years at the University.

I have only glanced at the requirements of the English provincial universities, and my impression is that their standard is much the same as the Scottish; but I shall leave the graduates of those universities to vindicate the status each of his own Alma Mater.

Let me assure Dr. Mercier that the general public "fashes" itself very little about our degrees and titles, the chief concern being to secure as much as possible from us for as little reward, in our senseless competition for clubs and underselling of each other in private work, as we, graduates and diplomates alike, are foolish enough to accept. It would serve us better to spend our energies in remedying these tangible matters than in the pursuit of vain degrees and phylacteries. Of the small public who take an interest in the different titles and qualifications, the well-informed appreciate each at its proper value. The ill-informed estimate a man's position by the number of letters he can append to his name, and, as the diplomate has more of the alphabet to play with than has the graduate, he is at no disadvantage in this respect.

Personally I have no objection to any body of men earning, begging, borrowing, stealing, or inventing for themselves whatsoever degrees or titles they may fancy; but, whilst they do so, I certainly deprecate all unwarrantable aspersions of other respectable corporations and their graduates.—I am, etc.,

JOHN DIVINE, M.D. Glasgow.

Gull, March 16th.

SOUTHWOLD LIBEL CASE.

IN order to remove certain misunderstandings that seem to have arisen, we are requested to draw attention to the exact words of the paragraph in which the opening of a fund on behalf of the defendants in this case was made known in the JOURNAL of February 6th, p. 353:

"Upon the suggestion of local members of the profession* who desire to give practical expression to their sympathy with Drs. Mullock and Tripp, of Southwold, a fund has been opened to assist them in defraying the heavy expenses which they have incurred as the result of the recent action which they were called upon to defend."

*The italics were not in the original.

By a printer's error, the date of Dr. Smith's letter published last week was printed February instead of March 6th.

Universities and Colleges.

UNIVERSITY OF LONDON.

MEETING OF THE SENATE.

A MEETING of the Senate was held on February 24th.

Appointment of a Royal Commission.

Attention was drawn to the announcement which had appeared in the press that a Royal Commission had been appointed to inquire into the subject of university education in London. It was reported "that the reference to the Commission had not been submitted or communicated to the University, and that the Government had, prior to the publication of the announcement, been informed that it should not be assumed, without opportunity for consultation, that the Senate would be an assenting party to any reference to a Commission in excess of, or inconsistent with, the resolution on the subject passed by them on December 2nd last."

D.Sc. Examination in Physiology.

The degree of Doctor of Science in Physiology has been conferred upon Dr. Frederick Hughes Scott, the subject of his

thesis being the relative parts played by nervous and chemical factors in the regulation of respiration. It was reported that, in addition, Dr. Scott had submitted other contributions to the advancement of science.

Laboratory of National Eugenics.

Mr. David Heron, M.A., and Miss E. M. Elderton were reappointed Research Fellow and Research Scholar in the Francis Galton Laboratory for National Eugenics for a further period of one year.

Grant from the Goldsmiths' Company.

A communication was received from the clerk of the Goldsmiths' Company intimating the renewal for a further period of three years of the Company's annual grant of £5,000 towards the maintenance of the Goldsmiths' College, New Cross. The cordial thanks of the Senate were accorded to the Company for their continued generosity.

Dates of Examinations for Medical Degrees.

It was resolved that in 1910 the second examination for medical degrees, Part II, should be held on the second Monday in March, and that the second examination for medical degrees, Part I, be held on the Thursday following the second Monday in March.

The B.Sc. (Pass and Honours) Examination in Physiology for External Students.

The Senate has resolved that in and after 1910 certain emendations should be introduced in the regulations for the B.Sc. (pass and honours) examination in physiology for external students (Blue Book, September, 1908, pp. 298-310).

Portraits of Former Vice-Chancellors.

The portraits of the following former Vice-Chancellors have been presented to the University, and have been framed and hung in the Vice-Chancellor's room: Sir John W. Lubbock, Sir John Shaw-Lefevre, Sir Edward Ryan, Sir George Jessel, Sir Julian Goldsmid, Sir John Lubbock (now Lord Avebury), Sir James Paget, Sir Henry Roscoe, Dr. A. Robertson (now Bishop of Exeter), and Dr. P. H. Pye-Smith.

Election of Representative.

Dr. Frederick Taylor has been appointed representative of the University on the General Medical Council in the place of Dr. P. H. Pye-Smith, resigned.

University Studentship in Physiology.

A university studentship in physiology of the value of £50 for one year will be awarded to a student qualified to undertake research in physiology. Candidates must be matriculated students or graduates of the University. Applications to be sent to the Principal by May 31st, 1909, from whom further particulars can be obtained.

EXTRAORDINARY MEETING OF THE SENATE.

An extraordinary meeting of the Senate was held on March 3rd, summoned by the Vice-Chancellor upon a requisition signed by six members, to consider the announcement which had appeared in the press regarding the appointment of a Royal Commission on the University, and to decide what action, if any, should be taken on behalf of the University. Eventually the Senate resolved to meet as a committee to consider the matter further on March 31st.

UNIVERSITY OF ABERDEEN.

UNIVERSITY COURT.

A MEETING of the Aberdeen University Court was held in Marischal College on March 9th, Professor Matthew Hay presiding, the Principal being still indisposed.

It was announced that Dr. William Day, late rector of the old Aberdeen Grammar School and at present a member of the Court, had intimated to the secretary the intention of himself and his brothers founding a scholarship, of the annual value of £100, in memory of their father, to be called the "James Day Scholarship in Education." Intimation was received that the committee in charge of the movement to erect a memorial to the late Professor George Pirie proposed that, subject to the sanction of the University authorities, the memorial should take the form of a stained-glass window in the antechapel of King's College Chapel. The Court, as well as the Senate, approved of the proposal, subject to the designs and plans being afterwards approved.

Gift to the Natural History Department.

Mr. R. Hay Fenton (London) has offered to the University, on certain reasonable conditions, his very fine collection of British birds' eggs. Four years ago Mr. Fenton lent the bulk of his collection to the Natural History Museum, Marischal College, and it has been of great interest and value to students and others. The collection numbers upwards of 7,000 specimens, and includes, as its greatest rarity, an egg of the extinct great auk. Mr. Fenton, in his letter intimating the gift, said: "In making this offer to the University of my native city, let me express the hope that it may be the means of stimulating Aberdonians at home and abroad, and especially graduates, to take an interest in and contribute specimens to the Natural History Museum, where, as a boy, I spent many a profitable and pleasant Saturday afternoon in the company of my father." The Court received the intimation with much satisfaction, and resolved to express its very cordial thanks to Mr. Hay Fenton for his most generous gift.

Resignation of Professor Ogston.

The following letter was received from Professor Ogston by the Secretary of the Court:

"As I feel that it would be in the interest of the University that its department of surgery should now be in the hands of a younger man than I am, I beg that you will submit to the University Court my regret that they will, under the provisions applicable to those professors who have attained the age of sixty-five years, be pleased to sanction my resignation of the chair of surgery, to take effect from the end of the present University year, by which time I shall have completed my sixty-fifth year and shall have held the chair of surgery for twenty-seven years. My object in thus early proffering my request is to ensure that my successor may have ample time to arrange his plans of teaching and be able to commence his duties at the beginning of the winter session 1909-1910."

This letter confirms the statement which Professor Ogston made to his class at the opening of the session in October. It is understood that among the candidates for the vacant post are Mr. J. Scott Riddell, M.V.O., M.A., M.B., Senior Surgeon, Aberdeen Royal Infirmary; Mr. John Maroon, M.A., M.B., Surgeon, Aberdeen Royal Infirmary; Mr. H. M. W. Gray, M.B., F.R.C.S., Surgeon, Aberdeen Royal Infirmary (all three are lecturers in clinical surgery to the University), and Mr. Alex. Don, M.A., M.B., F.R.C.S., Surgeon to the Dundee Royal Infirmary.

UNIVERSITY OF DUBLIN.

The following candidates have been approved at the examination indicated:

FINAL (PART II).—D. M. Moffatt, A. J. Stals, J. D. Kernan, H. R. Kenny, F. R. Sayers, C. G. S. Baronsfeather, D. J. Stokes, C. B. Jones.

* Passed on high marks.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

MEETING OF COUNCIL.

At a meeting of Council on March 11th, Mr. Henry Morris, President, in the chair, Mr. F. Richardson Cross was appointed Bradshaw Lecturer for the year, and the Sir Gilbert Blane medals were awarded to Staff Surgeon Charles Rowley Nicholson, H.M.S. *Egmont*, 1906-7, and Staff Surgeon Arthur William Bligh Livesey, M.B., H.M.S. *Bonaventure*, 1907.

His Excellency Dr. Nicolas Weliainoff, Privy Councillor of State and Professor of Surgery at the Imperial Military Academy of Medicine, St. Petersburg, who was elected an Honorary Fellow of the College in 1901, was introduced and signed the Roll.

The Admission of Women to the College.

The following proposed by-law was accepted, but again referred to the Committee by which it was drawn up, for further consideration:

1. Pursuant to the powers conferred by the Medical Act, 1876, and subject to the provisions therein and hereinafter contained, women may be admitted as Members and Fellows of the College and may obtain Diplomas in Dental Surgery on the same terms and conditions as men; and so far as it is necessary to give effect to this By-law words in the By-laws and Regulations of the College which import the masculine gender shall also import the feminine gender, and all proper alterations shall be made in the form of the Letters Testimonial, Diplomas, Certificates and Licences granted by the College.
2. Women shall not be eligible as Members of the Council or vote at or take any part in any election of a Member or Members of the Council, or attend any Meeting of Fellows or of Fellows and Members (except Meetings convened for the delivery of Lectures or Orations), or otherwise take any part in the government, management, or proceedings of the College.
3. Women shall not be eligible as Members of the Court of Examiners or for any Examinerhip to which the Council appoints.

Election of Representative.

Mr. Henry Morris was re-elected for a period of five years as the Representative of the College on the General Medical Council.

The May Examination.

Mr. William Wright was appointed Substitute Examiner for the May examination, in place of Professor Young, whose resignation was accepted with regret.

The Charter of the British Medical Association.

A committee was appointed to consider the petition of the British Medical Association for the grant of a Charter of Incorporation.

The Services.

ARMY ESTIMATES.—MEDICAL SERVICES.

Classification of Cases.

COLONEL E. B. HARTLEY (retired), of Ilminster, Somerset (late P.M.O. Cape Colonial Forces), writes: "One cannot help feeling glad to see in your issue of March 6th that the admissions to hospital of the regular army have been considerably reduced by 'an administrative improvement by which men with slight ailments are not removed to hospital, but are treated in barracks as out-patients' (I am quoting Mr. Haldane's sentence). I have always been surprised that this system was not followed years ago, for undoubtedly in times gone by thousands of soldiers have been admitted into military hospitals who would only have been treated by civil hospitals as out-patients."

During my twenty-six years' service in the regular forces of the Cape Colony the Daily Sick have been marched to the hospital and the medical officers have classified them as follows: "Hospital," "No duty," "Medicine and duty." The "No duty" men lived in the barrack-rooms, and were excused parades, guards, drills, sentry duty, and fatigues. They were not allowed to enter the canteen, nor to walk beyond the precincts of the barracks. These cases would be lesser ailments, minor fractures of the upper extremities, contusions, certain stages of venereal disease (of course not all) and trivial complaints generally. It was found that much expense and trouble to all concerned was saved in this way. The patients got well quite as quickly when out of hospital as in, and the hospitals were not crowded with a lot of idle listless men, a weariness to themselves and a bother to everybody else.

Many commanding officers, I know, will say a man must be doing his duty or be in hospital, and that they do not want a lot of idle men leading about the barracks and cantonments, a bad example to their comrades and a blot upon the normal smartness of a station, etc. Such ideas are very excellent, but they will not help the British taxpayer, nor will they keep the hospitals empty. The other classifications "Hospital," "Medicine and duty," explain themselves.

I venture to submit that some such plan as I have endeavoured to explain might be considered for adoption in H.M. Imperial Army.

THE ROYAL NAVY MEDICAL SERVICE.

GENERAL EXPENDITURE.

THE First Lord of the Admiralty issued with the navy estimates for 1909-10, published on March 12th, an explanatory statement. The total expenditure is this year estimated at £35,142,700. The estimate for the medical services, including the cost of medical establishments at home and abroad, amounts to £258,700.

THE COMMITTEE ON THE MEDICAL SERVICE.

The statement contains the following paragraph:

"The recruiting of the Naval Medical Service has for some time been a matter of anxiety to successive Boards of Admiralty. I have now appointed a Committee to inquire into the naval medical service, composed as follows:

Admiral Sir John Durnford, K.C.B., D.S.O. (Chairman).
Inspector-General James Porter, C.B., M.D., M.A. (Medical Director-General).
Surgeon-General Sir Alfred Keogh, K.C.B., M.D.
Mr. J. H. Brooks, Principal Clerk.
Sir William W. Cheyne, Bart., C.B.
Deputy Inspector-General William H. Norman, R.N.
Mr. G. L. Chesdale, C.B., F.R.C.S.
Mr. J. S. Barnes, Admiralty, Secretary.

We hope, with the able assistance of these gentlemen, that we shall devise some means of putting the Naval Medical Service upon a more satisfactory footing."

ROYAL ARMY MEDICAL CORPS (TERRITORIAL). ABERDEEN.

THE paragraph published in the issue of March 6th referring to the position of the training school of the Highland Division was apparently open to misconstruction, and gave rise to a wrong impression of the state of training of the corps in Aberdeen. It was not intended to convey the idea that little practical work had been done in connexion with the field ambulances, as this would have been very contrary to the actual state of affairs. Instructional classes have been held in a wide range of subjects, and a much larger amount of work has been done in this regard than was ever accomplished under the old volunteer system. With regard to the finance of the training school, certain developments have quite recently taken place and certain grants have now been received for the school. Before these grants were made the work was being carried on from the funds of the field ambulances, so that the actual training of the corps has not suffered in any way.

SECOND LONDON DIVISION.

The organization of the field ambulances of the Division is practically complete. No. 6 Field Ambulance was recognized last week, and there are now enlisted 7 officers and 209 men. Both Nos. 4 and 5 Field Ambulances are seven or eight above strength.

Of the General Hospitals No. 4 is recognized; in addition to the staff *à la suite* which is complete, it has 3 officers and 26 men, 17 additional men being required to complete it.

FIELD AMBULANCES.

LIEUTENANT-COLONEL J. H. STACY, Officer Commanding 2nd East Anglian Field Ambulance (Norwich), writes: I see the 3rd South Midland and the 3rd Northumbrian Field Ambulances are claiming to be the first of these fresh units up to full strength. I may say that the 2nd East Anglian Field Ambulance was full up at the beginning of the year except for one officer and one sergeant compounder. I think that their popularity is due to the schools of instruction for the regular army making the recruit feel that on joining he is getting an education in itself.

Medico-Legal.

THE RESPONSIBILITIES OF MAGISTRATES.

MEMBERS are probably more or less familiar with the case in which Dr. Hodgson of Crewe was made defendant for certain remarks with which, as Chairman of the local Bench, he announced his decision in certain cases before it with regard to the nature of the agreements as to some public-houses at Crewe. In announcing the decision of the Bench, Dr. Hodgson stated that the then opinion of the Bench was that Messrs. Walker had misled the magistrates. Messrs. Walker commenced an action against Dr. Hodgson claiming £10,000 damages. Mr. Justice Ridley ruled that there was no absolute privilege, and the matter was arranged, Messrs. Walker offering to admit that Dr. Hodgson's comments were made bona fide if he, on his part, would publicly state what he had really already admitted, namely, that his remarks, in view of the facts which subsequently came to his knowledge, were not justified. Dr. Hodgson is an ex-mayor of Crewe, a member and Vice-Chairman of the Cheshire County Council, and Chairman of the Education Committee. The following appeal has been issued, signed by, among others, the Right Hon. Sir John Brunner, Bart., M.P., Mr. H. Lever, M.P., Mr. James Tomkinson, M.P., Mr. W. J. Crossley, M.P., Mr. A. J. King, M.P., and the Hon. A. Lyulph Stanley, M.P.:

We feel confident that there are many who will be glad to join in relieving Dr. Hodgson of the heavy costs for which he has become liable in his defence of the action brought against him by Messrs. Walker.

A great burden has been cast on Dr. Hodgson through the discharge of his public duties as a magistrate, and by his fight on a point which is of great public interest—namely, whether magistrates have an absolute privilege when sitting as members of a Licensing Committee.

It would be a fitting recognition of Dr. Hodgson's long, varied, and unsparring services to Cheshire, and of the esteem in which he is held, that he should be relieved from a personal responsibility which he has incurred from his action in a public and representative capacity.

The total amount of Dr. Hodgson's costs in the case will probably amount to £4,000. Subscriptions will be received by Aldermen McNeill, Herdman Street, Crewe (the honorary treasurer of the fund); and by Alderman C. H. Pedley, C.C., Westminster Buildings, Crewe (the honorary secretary); or they may be paid to the credit of the Dr. Hodgson Testimonial Fund, Parr's Bank, Crewe.

CONTRACT PRACTICE.

A CASE of considerable interest to medical men engaged in contract practice was recently decided in the Cheltenham County Court.

The plaintiff was the medical officer to a friendly society, and he sought to recover fees from a member of the society for seeing a fractured clavicle and affixing a splint. The plaintiff admitted having examined the defendant some years previously and certifying him as a fit person to become a member of the society, but he based his claim on the facts that he had no information as to whether defendant had in fact become a member, that defendant had omitted to produce his card of membership, as plaintiff contended he was bound to do, and that his payments were in arrears. For the defence it was denied that defendant was in arrears, and was contended that there was no obligation on him to produce his card.

Judge Ellicott held that the question of a member being in arrears or not was not a question for the surgeon, but as the rules of the society imposed certain duties on the surgeon, there was a correlative duty on the members to prove their title to his services. This the defendant had not done, and he accordingly gave judgement for the plaintiff with costs on the *a* scale, as the case was one that concerned a large number of people. The medical man concerned is to be congratulated on the result of the case and on his determination in fighting it.

CORONERS AND NECROPSIES.

A COLONIAL correspondent, who signs "Witness," asks: Is it in accordance with British usage and custom that a medical coroner should attend and witness the *post-mortem* examination he has directed to be made preparatory to an inquest, and that he should remark upon and discuss the pathological findings during the conduct of the necropsy?

* We are pleased to say that conduct described by our correspondent is not usual with coroners in England, and we think that, as he has afterwards to preside over the jury, with himself deliberate on the case in question, it would be wiser and more judicial if he brought his mind to bear upon the sworn evidence given before the court unprejudiced by observations he may have made at the *post-mortem* examination. We further are of opinion that, having issued his order for a *post-mortem* examination to be made, he should rely upon the report given in evidence at the inquest by the operator, and not present himself at the necropsy, as on the occasion in question.

FEES FOR MEDICAL EVIDENCE.

CHESHIRE SURGEON writes that he has been subpoenaed to give evidence as to the testamentary capacity of a deceased

patient, and asks the following questions: (1) Is he at liberty to charge any fee he likes, with travelling expenses? (2) Or is he compelled to accept the statutory fees and allowances? (3) Can he claim from the solicitors in the case fees for consultations, letters, etc.? (4) Is his evidence regarded as expert evidence or merely evidence as to facts?

(1) Yes; but, unless he gets a written promise to pay from the party who subpoenas him, he will be unable to recover more than the legal allowance. (2) In the absence of any binding agreement to pay more, he must accept the legal allowance. (3) He should stipulate for these expenses beforehand, otherwise he might have a difficulty in recovering them. (4) No, it is ordinary professional evidence. Expert evidence is properly that given by an outside witness who has nothing to do with the case personally.

Medico-Ethical.

The advice given in this column for the assistance of members is based on medico-ethical principles generally recognized by the profession, but must not be taken as representing direct findings of the Central Ethical Committee.

CIRCULARS TO PATIENTS.

X. X.—There can be no objection to the terms of the circular proposed, and no criticism is likely to arise so long as it is sent only to persons who are actually the patients of the firm.

CIRCULARS TO THE PROFESSION.

R. N. D. B.—We can see no objection to our correspondent sending such a circular to the medical men in his neighbourhood, but would suggest that references and not testimonials should be enclosed.

CONTRACTS NOT TO PRACTISE.

M. W. W. had better consult a solicitor, as everything depends on the exact terms of the bond. In all probability the contract is valid, but courts take into consideration the reasonableness of restrictions.

A QUESTION OF FEES.

HARD HIT.—Would it not be better to write a friendly letter asking for particulars, as no memorandum appears to have been kept of the number of visits? If this were known, the amount might be estimated, and we do not think the fees should exceed the rate of three visits for a guinea. Of course, the out-of-pocket expenses would have to be paid in addition, but many public authorities report on diphtheria swabs and supply antidiphtherial serum without charge.

A NEW FORM OF ADVERTISEMENT.

NO ADVERTISEMENTS complains that he has been worried by a representative of the "Court Something-or-other," who is collecting information from medical practitioners for a work which he says is "read by laymen."

"* We sympathize with our correspondent, but fear that all he can do is to close his doors, as far as possible, against impudent canvassers.

A DISCLAIMER.

DR. ARTHUR S. MORLEY (London, W.C.) writes: I have recently written certain articles on the medical aspects of accident insurance for the *Accident Year Book*. I regret to see that in their advertisements of the book in certain insurance journals the publishers have advertised my name and mentioned my connexion with a large insurance company. They have done this without my knowledge or consent, and I should be greatly indebted to you if you would publish this letter in order to free me from the suspicion of being a party to what might be regarded as a very objectional form of advertisement of myself.

MEDICAL ADVERTISING.

WITH reference to the paragraph under this heading, published in the *JOURNAL* of January 9th, we are informed by the practitioner concerned that as soon as he became aware that the poster and handbill had been issued he took effectual steps to prevent their further circulation, and as this fact was known to the secretary of the local Branch he complains that any notice should be taken of it in the *JOURNAL*. We are glad to know that the advertisements were issued without the consent of the practitioner concerned, but we would point out that in the case to which we referred the same plea was put forward. Ignorance on the part of the practitioner cannot absolve him from responsibility, as this would open the door to unlimited advertisements by club authorities. The officials of the society should know that they risk its existence, in so far as it is dependent upon the services of a registered medical practitioner, if they issue advertisements of the kind sent to us.

Public Health

AND

POOR - LAW MEDICAL SERVICES.

POOR LAW MEDICAL OFFICERS' ASSOCIATION OF ENGLAND AND WALES.

A council meeting of this association was held at 9, Cophthall Avenue, E.C., on March 11th, Dr. D. E. Baiding being in the chair.

Dismissal of Medical Superintendent.—The honorary secretary reported that the Local Government Board had asked to be allowed to send the memorial and papers of the dismissed medical superintendent, whose case was considered at the last meeting (*BRITISH MEDICAL JOURNAL*, February 20th, p. 559), to the board of guardians. After obtaining that gentleman's consent the request had been acceded to.

Audit of Guardians' Accounts.—In the case of Brand and the Driffield Guardians (see report of last meeting) the association had been represented by Mr. Jennings before the Local Government Board auditor, and the latter had surcharged the guardians £13 18s. 11d. It was likely that the surcharge would be increased at the next audit.

Medical Inspection of School Children.—Further evidence was brought before the council of extra work done by the Poor Law Medical Officers being put upon Poor Law medical officers in consequence of recent legislation. A communication had been received from a member, enclosing a letter from the clerk to his guardians, requiring him to visit and examine twenty children to ascertain whether they were properly fed. Some of the council thought that such an Order was illegal, but the honorary secretary pointed out that the district medical officer was bound to attend to any order issued by the relieving officer, or by the board of guardians in its corporate capacity, although complaint might be made afterwards to the guardians or Local Government Board. The clerk's letter amounted to an order from the Board. He thought this was a very proper case to bring before the Local Government Board, as the evidence was so clear, but the complainant would not give his permission for fear of losing his vaccination appointment if he made any complaints.

Royal Commission on the Poor Laws.—The council then considered the report of the Royal Commission on the Poor Laws. Satisfaction was generally expressed at the justice done to the Poor Law Medical Service, and the frank recognition of its valuable and unselfish public work in the past despite the glaring inadequacy of the remuneration; but exception was taken to the proposed abolition of that service in the future. In the opinion of the council the existence of such a service was absolutely necessary for the public good, and reform should be directed to making it more efficient. After much discussion the council decided that more time would be required to deal properly with the report, but it thought that some preliminary resolutions might be considered concerning which there would probably be practical unanimity among all Poor Law medical officers. The following resolutions were finally put and carried unanimously:

1. That this council desires to express its grateful acknowledgement of the unanimous testimony borne by the Royal Commission to the value of the past services of Poor Law medical officers, and its recognition of the disadvantages under which they have laboured and the inadequacy of their remuneration.
2. That, in the opinion of this council, it is impossible for Poor Law medical relief to be organized on a provident basis, as the only proper recipients of such relief are, by reason of their poverty, unable to contribute anything; that those able to contribute are proper objects for charitable assistance.
3. That the council views with disapprobation the proposal to draft the State poor law to provident medical institutions, that, in its opinion, it would result in converting the same into Poor Law institutions, mainly supported by the rates; that it would be disastrous to these institutions by driving away many, if not all, of that class of whom they were specially created. Further, that it would largely increase the number of the State poor by adding to them many of the poorer members of provident medical institutions, and by so doing would inevitably cause great injury to the whole medical profession, especially the practitioners in poor districts.
4. That the council strongly condemns the proposal to make every medical practitioner a Poor Law medical officer, and it does so for the following reasons:
 - (a) That it would be many times more expensive than the present system.
 - (b) That the value of the work done could never be properly tested, as no system of Local Government Board inspection could deal with so widely extended an arrangement for Poor Law medical relief.
 - (c) That it would largely tend to provide free medical relief to all poor persons, and to increase, rather than diminish, the pauperization of the nation.
 - (d) That the interests of the sick State poor would be far better attended to by a special service, the members of which were paid adequately, and whose work was capable of proper inspection.
5. That the council strongly disapproves of the proposal to allow a poor person to claim State medical aid without the intervention of a relieving officer or assistant relieving officer. If it were to be opened the door widely to gratuitous medical relief to all members of the poorer classes; that it is no part of the duties of a Poor Law medical officer to decide as to the right of a poor person to State relief; and, as in any widely extended system it would be necessary to pay for the items of work done by the medical officer, it would be a direct incentive to the latter to admit too readily the claims of poverty. That for the protection

of the ratepayer it is absolutely necessary that there should be a skilled lay officer to decide who are proper applicants for medical relief. That in thickly-populated areas there is no hardship in requiring applicants to get an order from an assistance officer, and that instances of the deserving State poor being deterred from applying to the Poor Law medical officer through having first to obtain an order, are in urban districts conspicuous by their rarity.

DISINFECTION.

BELFAST AND EAST ANGLIA.—Spraying with a solution of formalin is a very common and excellent method of disinfecting rooms after they have been occupied by scarlet-fever patients. The furniture should be sprayed with the solution, 1 part in 40 of the 40 per cent. solution, and should then be thoroughly cleaned with soap and water.

INFECTIOUS DISEASE IN HOTEL.

MIDLANDS.—(1) The manager of a hotel can insist, after giving suitable notice, upon any guest quitting his hotel. (2) In a county court action by an innkeeper to recover the cost of disinfecting rooms which had been occupied by a guest who had died from consumption while in the inn, it was held by the county court judge that the cost could be recovered on the ground that the law would imply a contract on the part of the guest to pay for any extra expense properly incurred by the innkeeper as a consequence of the reception of the guest. A claim for damages for the loss of use of rooms during the time of disinfection was not successful (*Law Times* (1899), vol. cvii, p. 101). No references or names of parties are given. Quoted in Copnall's *Infectious Diseases and Hospitals*.

MEDICAL CERTIFICATION OF WORKHOUSE LUNATICS.

H. C., who writes with reference to a short article on the above subject which appeared in the *British Medical Journal* of March 6th, p. 630, refers to several lunacy cases which he had himself attended, and which were removed to the workhouse and thereby passed altogether out of his hands, though subsequently sent to an asylum. In reference to a fourth case of somewhat similar character, he says that he wrote to the relieving officer asking whether it would not be possible for the lunacy of patients detained in a workhouse to be certified (if necessary) by their own previous medical attendants, with the result that he was called upon to certify this fourth. Later still another case cropped up, and our correspondent was asked by the relieving officer to call at the workhouse to certify to the lunacy, which he did. He further says: I should like your opinion on this matter as presented by myself, in view of the fact that you have expressed the opinion that soliciting engagements to certify to lunacy cases in a workhouse was an unwelcome claim." He adds: "Had I solicited to certify cases not my own I should have agreed with you."

"* If the account given is strictly correct, which we have no reason to doubt, namely, that our correspondent has only certified cases which had been previously under his own care, we cannot regard his going to the workhouse for this purpose and subsequently certifying as being in any way a breach of professional etiquette. Should any such cases recur, we think he would show a wise discretion by calling or leaving his card on the medical officer of the workhouse before visiting the patients, but as to this he really ought to be a better judge than ourselves.

Obituary.

SIR ARTHUR RENWICK, M.D., F.R.C.S.,

SYDNEY, N.S.W.

The death took place in Sydney on November 22nd last of Sir Arthur Renwick, M.D., F.R.C.S. Edin., in his 72nd year.

He was one of the first graduates in Arts in the University of Sydney, and as there was no medical school in Sydney in those days, he proceeded to Edinburgh, where he took the degree of M.D. and the diploma of F.R.C.S. He returned to Sydney, and soon acquired a leading practice. He was elected the first President of the New South Wales Branch of the British Medical Association. While he was still quite a young man he was elected to the Honorary Staff of the Sydney Hospital, and he remained connected with that Institution up till the time of his death, though not in the capacity of honorary medical officer, but as President. He also early became connected with the Benevolent Asylum, and the Institution for the Deaf and Dumb. He was President of the Medical Board for many years, and was always most regular and punctilious in his attendance at all the meetings over which he was accustomed to preside. He was also a member of the Senate of the University of Sydney, and had served in the office of Vice-Chancellor on several occasions.

Many years ago he entered Parliament, and represented the constituency of East Sydney. He was at different times Minister of Mines and Minister of Education. Later on he was elevated to the Legislative Council, and he was a member of that body up to the time of his death. In the year 1892 he was appointed Executive Commissioner for New South Wales to the Chicago Exhibition, and two years later he received the honour of knighthood for his services in that capacity.

Sir Arthur was attacked with influenza some months before his death, and this weakened his heart so much that he was never able again to take up his duties. His funeral was largely attended by members of the profession and representatives of the various charitable institutions with which he had been connected during his long and useful life. His death has removed one of the most active philanthropists of Australia.

JAMES HURD KEELING, M.D. Edin., F.R.C.S. Eng.,

CONSULTING SURGEON TO THE HOSPITAL FOR WOMEN AND
ROYAL HOSPITAL, SHEFFIELD.

DR. J. HURD KEELING, who had been in failing health for several years, died at his residence in Sheffield on March 15th, aged 77. He was the son of the Rev. John Keeling, a well-known Wesleyan minister, who at that time resided at Malta. The family returned to England while the boy was still young, and he attended a well-known Wesleyan school at Woodhouse Grove, near Leeds. He prosecuted his medical studies at Edinburgh University, which he entered in 1848; he took the degree of M.D. in 1852, and he afterwards visited London (where he took the diplomas of M.R.C.S. and L.S.A.), as well as Paris and Vienna, for purposes of medical study. He then became an assistant to Dr. Thorpe at Staveley, but when the Russian war broke out in 1854 he went as surgeon to the second regiment of the Turkish contingent, and his services in that capacity were rewarded by the decoration of Officer of the Order of the Medjidieh. After the war he returned to Staveley, but in 1858 settled in Sheffield; here he acquired the practice of Dr. Cheetham, settling at Crow Tree House, Broomhall Street, then a country residence in the midst of a big garden; there he lived with his sister until he removed to Glossop Road a few years later. In 1860 he was appointed Lecturer on Medical Jurisprudence at the Sheffield Medical School, thus beginning an association with the teaching of medicine in Sheffield which lasted nearly forty years. When he accepted this office he made the stipulation that toxicology should be taught by a chemist, and Dr. Allen accordingly undertook this part of the subject. Four years later he was appointed Lecturer on Physiology in the Medical School, the affairs of which at that time were in so unsatisfactory a condition that it had been proposed to close it. Dr. Keeling was one of those by whose efforts the school was reconstructed in 1865. Dr. Keeling then resigned the lectureship in physiology, and was appointed, in conjunction with Dr. Aveling, Lecturer on Midwifery and Diseases of Women, and continued to lecture on this subject for thirty-two years.

When the Hospital for Women was founded in 1864, Drs. Keeling, Aveling, and E. Jackson were appointed the medical officers, and afterwards, through the generosity of Mr. Thomas Jessop, the Jessop Hospital for Women was erected. Dr. Keeling took a great interest in the hospital, and not only himself gave generous financial assistance, but was instrumental in obtaining a considerable proportion of the funds required for its extension in 1902. The position attained by the Jessop Hospital as one of the leading medical charities of Sheffield was largely due to his efforts, and when he retired in 1906 the board elected him Honorary Consulting Medical Officer, and placed on record its high appreciation of his valuable and disinterested work. A proposal to present him on behalf of the medical profession with a public testimonial on this occasion was abandoned owing to Dr. Keeling's own objections. Dr. Keeling was elected Surgeon to the Royal Hospital, Sheffield, in 1862, an office he retained for twenty-five years. When the British Medical Association met in Sheffield in 1876 Dr. Keeling was associated with the late Mr. A. Jackson in the office of Honorary Local Secretary, and his friends would have been glad if he could have been persuaded to have accepted an honorary official position at the memorable meeting last year. For many

years Dr. Keeling took an active part in the work of the Sheffield Medical Society, and contributed many papers from time to time, although he does not appear ever to have published any of them. He was a man of marked ability, well versed in medical literature, and possessing a ripe and varied experience. In disposition he was reserved, delighting in secret kindnesses and self-sacrificing labour, but receiving any acknowledgement of his good deeds with characteristic brusqueness.

W. H. DAY, M.R.C.S., L.S.A.,

NORWICH.

THE death occurred, after a long illness, on March 15th, at the ripe age of 85, of Mr. W. H. Day, of Norwich.

William Hanks Day, who was descended from an old Norwich family, several of whose members had been very prominent in the life of the city, was born in 1824. He was a son of Mr. William Day, for over forty years clerk to the magistrates. He received his medical education at St. Thomas's Hospital, and obtained the diploma of M.R.C.S. in 1845, and that of L.S.A. in the following year.

After acting for a short time as surgeon to the Reading Dispensary, he entered into partnership in 1849 with Mr. W. P. Nicholls, then a well-known practitioner in Norwich. Eighteen years later, the partnership having come to an end, Mr. Day began to practise on his own account. For many years he was medical officer to the Lakenham district, and was also surgeon to the Jenny Lind Infirmary for Children, the Maternity Charity, and the city gaol. For forty-two years he was surgeon to the Girls' Hospital School. His practice brought him much into contact with the poor, and he discharged his duties with such solicitude and conscientiousness that he received the very unusual tribute of a testimonial got up by the parochial poor entirely on their own initiative. Mr. Day had at one time the largest obstetrical practice in the Norwich district, and had, it is said, attended as many as 8,000 confinements.

In his earlier years he was fond of amateur theatricals, and turned his capabilities in that respect to account to assist the volunteers, a service in which he took a great interest.

Mr. Day was Chairman of the Committee which raised the memorial fund to the late Mr. William Cadge, and his last public appearance was at the ceremonial of the unveiling of the memorial window erected from the proceeds of that fund in December, 1904.

Mr. Day married in 1849, and leaves five daughters, one of whom is the Matron of the Norwich Grammar School.

We are permitted to publish the following appreciation of Mr. Day, contributed by Dr. Michael Beverley to the *Eastern Daily Press*: The Dean of our local faculty, after a long and to him weary waiting, is gone to that rest which he has so earnestly anticipated. It is true that he found a solatium in his books and his facile pen, and to the last continued to take a keen interest in all the current topics of the day. His contributions to your columns were not infrequent, and often under a thinly-veiled anonymity his friends detected the well considered and pointed criticisms so characteristic of the man. But, in spite of this and the treasures of a well-stored mind and memory, I know of no one who felt so keenly his enforced inaction as William Hanks Day. To those of us—and but few now remain, who have pleasing reminiscences of Mr. Day in his prime—we remember him as one of the hardest-worked medical men in the city of Norwich, greatly respected by his colleagues, beloved by a large clientele of patients of all classes, a *persona grata* wherever he went, especially in Lakenham, where his name was a household word. At all times, day and night, in all weathers, he might be seen driving about with an old-world-looking coachman, whose face was as familiar to the man in the street as his master's. William Day was a fine example of the cultivated general practitioner of the old school. He was never known to commit a breach of professional etiquette or to be guilty of a mean action. *Noblesse oblige* found in him a true exponent, and this was felt and appreciated by his fellows. The last work in which, after his retirement, he engaged, to him a real labour of love, was the chairmanship of the committee by whose exertions a memorial

window was placed in the Cathedral to the memory of his old friend, Mr. Cadge. All of us who served under him can bear testimony to the enthusiasm which he threw into this very considerable undertaking, the accuracy of his artistic taste and judgement to which was due the splendid work of art which appropriately illustrates the life and work of a great surgeon. Nor can those who were present at the unveiling in the Cathedral ever forget the pathetic scene, and the deep feeling evinced by our octogenarian leader, when he read the dedication (composed by himself) in the presence of the President of the College of Surgeons, and his colleagues on the Council, of medical men from far and near, and a crowded congregation of his fellow citizens. The memory of William Day will ever remain green amongst all who were privileged to claim his friendship.

We regret to have to announce the death of Dr. ROBERT HENRY COALL, which took place at Cannes on February 20th last, from heart failure following pneumonia. Dr. Coall, who was the son of Mr. Talbot Coall, of Kingstown, Dublin, was born on February 20th, 1859. Educated at the Carmichael School, he took the diplomas of L.M. Rotunda Hospital (special certificate) in 1881, L.R.C.S.I. in the following year, and in 1884 L.R.C.P. and L.M. Edin. He was Resident Medical Officer to the City of Dublin Hospital, and afterwards commenced practice near Leicester. A few years later, his success having justified the removal, he settled in Bedford Square, London, and as practice increased removed to 65, Brook Street, Grosvenor Square, where the illness commenced from the effects of which he ultimately died. It is now some thirteen years since an attack of hæmoptysis warned him that the success which had attended his professional career had been bought at too great a sacrifice of strength, and he was obliged to relinquish to an increasing extent the large practice which he had gained in London, and spend more of each year in a warmer climate. Dr. Coall was an example of the cultured practitioner; his patients became his friends, nothing that he could do for their welfare was too much trouble, and although regular attendance of recent years was not possible for most, his yearly arrival in the summer was eagerly anticipated by them and his advice highly valued. Few who met him in recent years had any suspicion of the fact that he was an invalid; only his great strength of character and unselfish disposition, however, enabled him to go about as he did. His death has come as a surprise, therefore, to many, and to these it will be a consolation to know that although he died abroad, he had devoted friends with him during his last illness, and received every attention at the hands of Dr. Carr, of Cannes. We may add that he was also seen in consultation by Sir Dyce Duckworth, Dr. Osler, and Professor Lingard.

Dr. FREDERICK IRVING KNIGHT, of Boston, who died on February 20th, was one of the pioneers of laryngology in America. Born in 1841 he graduated at Yale in Arts and at Harvard in Medicine in 1866. Afterwards he studied in Vienna, London, and Berlin. In 1872 he was appointed instructor in the diagnosis of diseases of the chest and in laryngology at Harvard. This was the first clinic of its kind in New England. In 1886 he was made Clinical Professor of Laryngology, a position which he held until 1892. Dr. Knight was one of the founders of the American Laryngological Association and one of its early presidents. He was also President of the American Climatological Association, of the Boston Society for Medical Improvement, and of various other scientific bodies. He took a prominent part in the movement against tuberculosis.

DEATHS IN THE PROFESSION ABROAD.—Among the members of the medical profession in foreign countries who have recently died are Dr. Heinrich Brat of Berlin, well known by his writings on industrial hygiene, aged 41; Dr. N. Pravossud, Lecturer on Ophthalmology in the University of Moscow, aged 48; Dr. André Boursier, Professor of Gynaecology in the University of Bordeaux, and President of the Society of Anatomy and Physiology and of that of Medicine and Surgery of that city, aged 58; and Dr. Hugo Gnaindinger, for many years Director of the Crown Prince Rudolph Children's Hospital, Vienna.

Letters, Notes, and Answers.

BRITISH MEDICAL ASSOCIATION AND BRITISH MEDICAL JOURNAL

THE offices of the British Medical Association and of the BRITISH MEDICAL JOURNAL are at 429, Strand, London.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 429, Strand, London, W.C.; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Office, 429, Strand, London, W.C.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Articulate*, London. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate*, London.

TELEPHONE (National).—
2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.
2630, Gerrard, BRITISH MEDICAL ASSOCIATION.
2634, Gerrard, MEDICAL SECRETARY.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should send them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL, and not at his private house.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

ETIOLOGY OF SPLENIC LEUKAEMIA.

SCOTT'S asks: Is splenic leukaemia known to follow carbon monoxide poisoning? As for instance in these circumstances—where a man has been exposed to carbon monoxide poisoning three times in twelve months and dies within the following year from splenic leukaemia. Also can there be any connexion between splenic leukaemia and malignant disease of the spleen? What authorities can be quoted?

RESULTS OF THE "KNOCK-OUT" BLOW IN BOXING.

R. W. M. writes: In view of the great booming of boxing now, when we hear of matches and competitions, amateur and professional, on every side. Lamentous to inquire into the results, or rather the after-history of those men who have been "knocked out." Can any one tell the after-history of any of these men? Some are "knocked-out" by blows on the angle of the jaw, or rather I should say the point of the chin, others by blows over the heart, and a third lot by blows over the solar plexus. To me, this seems the most serious. I understand that Fitzsimmons "knocked-out" man after man by blows over the solar plexus, that the men fell groaning, and were carried from the ring in a state of more or less insensibility. Can any one tell the after-history of those men? Did they recover perfectly, or were there any evil effects left, and what were the after-symptoms? I have heard that many "never were themselves again," but as to that I do not know.

ANSWERS.

J. L. M.—(1) Messrs. Holloway and Webb, Limited, military camp outfitters, 347, Cable Street, E., inform us that a well-made military tent used, say, twice in each year, has a life of about five years. When stored it should be put away perfectly dry and in a dry place. (2) Berthou tents are used for cases of enteric fever. (3) A joint hospital board decides for itself which infectious diseases shall be admitted into the hospital under its control.

FRENCH MEDICAL PERIODICALS.

FRENCH.—There are a multiplicity of periodicals suitable to our correspondent's purpose. Of those published in Paris, *La Semaine Médicale* (53, Avenue de Villiers, foreign subscription 15 francs, subscriptions commence January 1st, back numbers being supplied) would perhaps prove most satisfactory at the present time. Among the few monthlies, the *Archives Centrales de Médecine* (25, Rue de l'Ecole de Médecine, foreign subscription 18 francs, commencing from any quarter-day stands highest. Other journals are *Le Progrès Médical* (46, Rue des Ecoles, 12 francs), *La Tribune Médicale* (152, Rue de Valenciennes, 12 francs), both weeklies; and the *Gazette Médicale de Paris* (1, Rue Casimir Delavigne, 7 francs) a fortnightly publication.

LETTERS, NOTES, ETC.

ERRATUM.—In the second line from the end of Dr. Horace Dobell's letter on Sleep and Want of Sleep (BRITISH MEDICAL JOURNAL, March 13th, p. 691), for "Ft. guttae 3iv" read "Ft. guttae 3iv."

AN APPEAL TO MASONS.

MR. SYDNEY GRAHAM, M.R.C.S., F.R.C.P. (Watchet, Somerset), writes: Will you permit me through the columns of your JOURNAL to make an appeal to all professional brethren who are Freemasons to give their assistance in the following case: Dr. John Henry Sharpe, aged 45 years, who was formerly in practice at Hantspill, Bridgwater, who held the office of Medical Officer and Public Vaccinator under the Bridgwater Board of Guardians for fourteen years, and a member of the Highbridge Lodge No. 291 (W.M. 1895 and Secretary for three years; also W.M. Mark Lodge No. 191, and P.Z. of Chapter 291), had, unfortunately, in 1904 to give up his practice owing to the development of ataxic symptoms. Since that time he has not been in a position to earn anything owing to the state of his health, and he has no private means. He has a wife and six young children dependent upon him, and by the kindness of his friends and craft he has been greatly aided in getting them educated, and he now ventures to make a further appeal to charitable Masons to help him to get his son, Edward Herbert, aged 10, into the Royal Masonic Institution for Boys. This appeal would not be made if there was any probability of an improvement in Dr. Sharpe's physical or financial condition, and in proof that the case is one thoroughly deserving of the brethren's sympathy and support, I am permitted to say that the application is supported by Dr. Vereker, Langport; Dr. F. C. Berry, Burnham; Dr. N. Burns, Highbridge; Dr. C. R. Ashop, Sherborne; and the Ebury Obsequy Society of Somerset. Any members holding votes in either of the Masonic charities are earnestly requested to forward them to T. F. Norris, Esq., Charity Delegate, Highbridge, Somerset, as soon as possible, as the election takes place in April.

BOYS' RACES.

MR. J. HERBERT FARMER (London, W.) in the course of reply to criticisms, writes: My critics carefully avoid or carelessly miss the point of the medical opinion to which I was privileged to give publicity. You will remember that five of the most eminent medical authorities Britain possesses—Sir Lauder Brunton, Sir Thomas Barlow, Sir Alfred Frigg, Dr. James F. Goodhart, and Dr. W. Hale White—speaking from their personal experience and that of their professional colleagues, emphatically condemned, in their letter to me, races exceeding one mile in distance for the average healthy schoolboy under the age of 19. Yet schoolmasters are so eager to do so, because they themselves have not known cases of injury through long-distance racing, such cases do not occur; whilst some persons evidently have failed to realize the essential difference between (a) a long-distance race for a prize in which the competitors will gamely struggle along till they drop in their anxiety to win the cup; and (b) road or cross-country runs, which are taken merely for purposes of exercise, and in which the boys can and do enjoy frequent restful "breathers" whenever they begin to feel the warnings of exhaustion.

DR. HERBERT.

IN its issue for February 27th the *West London Gazette* notes that on the 22nd of the same month the *Star* and the *Morning Leader* settled out of court, by payment of agreed damages, actions for libel brought against them by Dr. P. Z. Hebert of Marylebone. They had previously published expressions of apology and regret. A record is added of a large number of other papers which at earlier dates adopted a similar course. The libel consisted in the publication some two years ago of an account of an affair near Paris in which Dr. Hebert was wounded. It was alleged that the principals in this affair were a gang of swindlers carrying on a matrimonial agency. Dr. Hebert being their English confederate. The affair was the subject of very prolonged police inquiry, but eventually all charges against Dr. Hebert were dismissed.

THE DOMESTIC PREPARATION OF SOURD OR CURDLED MILK.

G. R. G. writes: A patient who has suffered from colitis has been taking curdled milk daily with much benefit. The milk has been curdled by the addition of lactic acid tablets at a temperature of 104° F. and from a pint and a-half to two pints has been taken each day. Latterly he has been in the habit of adding to the fresh milk along with the tablets a small quantity of the whey from the previous day's "brew," and he finds that this considerably hastens the curdling, which with the tablets alone takes from eight to ten hours. But it also makes the product much more sour and acid, and I have my doubts as to whether it is a wise proceeding, as I think it is likely that other acids and ferments may be present, which are undesirable. Can any of your readers who have had experience of the curdled milk diet give advice on this matter?

MR. JOHN G. HUNK (Duns) writes: It became my duty some time ago to provide a daily supply of curdled milk. Because of the difficulty which many find in providing the same, I think it worth while to detail the method used. The milk was just brought to the boil at any convenient time (say in the forenoon), and allowed to cool in the vessel in which it had been boiled. When sugar was dissolved in the milk this was done immediately on its removal from the fire. (At say)

10 p.m. the cooled sterilized milk was skimmed and gently heated up to 106°-110° F. in the original saucapan. (Rewarming cold sterilized milk at this stage is more convenient than boiling fresh milk and allowing its temperature to drop to that mentioned.) The milk was then inoculated with one of the various lactic acid bacilli preparations and poured into a Thermos flask, previously warmed. After corking and shaking, the flask was laid aside overnight. Incubation went on, with no further attention whatever, and the following morning the milk was curdled and in good condition for being used as an article of diet or as a therapeutic agent. At the temperature mentioned nine or ten hours in the flask was found sufficient. When sufficiently curdled the flask was thoroughly shaken and the milk poured into a jar, which was then kept in a cool place during the day till the milk was all used. This process was repeated daily, over a long period, and was found to be the easiest and best method of preparing curdled milk in the home reasonably free from contamination by extraneous organisms. By altering the hour and the temperature (within limits) at which the process is started the milk can be brought to its best condition at any desired hour. That hour is generally the breakfast hour. It is necessary to keep the flask and cork clean by means of alkaline water, when not in use during the day, but in the evening, before use, they must be thoroughly freed from alkali before the cycle begins again. I am encouraged to write this note because of complaints I have heard that curdled milk is difficult to prepare in the home. I find that by the method described above it can be prepared as easily as many other articles of diet, and that its preparation can be undertaken by any intelligent person. The milk used must contain no preservative whatever.

THE APPLICATION OF MENDELISIAN RULES TO MAN.

DR. H. DRINKWATER (Wrexham) writes: I am sorry that Professor Karl Pearson is again guilty of misrepresentation, though, no doubt, it is unintentional on his part. At the end of his last letter he refers to "popular lectures and magazine articles," and in the second paragraph of the same letter to "a public lecture given by" me on Mendelism. Now, I have not, so far, written any magazine article, and the lecture to which he refers was given as a presidential address to a medical society, and can scarcely be termed "public." The professor's conclusions as to the effects of the views I have expressed in previous letters may be quite correct, but they by no means prove that my views are wrong, and whatever theoretical considerations may be involved I can come to no other conclusion, and I do not see how any else can come to any other conclusion, than that that part of Nettleship's chart which includes all the abnormalities is as strictly Mendelian as anything with which we are acquainted, and containing the same amount of material.

LYNN THOMAS AND SKYRME FUND.

Twenty-Second List of Subscriptions.

MR. WILLIAM SHEEN, M.S., F.R.C.S. (2, St. Andrew's Crescent, Cardiff), Honorary Secretary of this Fund, desires to acknowledge the following subscriptions:

IS CANCER CURABLE?

DR. ALEXANDER DUKE (London, W.) writes: The various vaunted cures for this terrible disease having all been found wanting, the interesting question arises, Which is most difficult, to diagnose the disease without doubt or cure the same when discovered to a certainty? I venture to ask the following questions: (1) Is cancer curable by operation? (2) If so, what time must elapse from date of operation till patient can be positively certified as free from the disease? (3) Can the diagnosis of uterine cancer be made to a certainty by any means at our disposal (including the microscope)? (4) Cancer being a constitutional disease manifested by local signs (somewhat like tubercle), how can the removal of the various local manifestations arrest the disease *in toto*, or prevent it showing itself by metastasis? Oral sepsis having been found contributory to the various forms of toxæmia, it might be interesting to make inquiry as to the state of the mouth in undoubted cancer cases. Probably when the real cure is found it will be doubted, reminding one of the old fable: "A wolf! a wolf!"

LIME: AN OLD SCOTTISH CUSTOM.

DR. J. A. WILSON (Cambuslang) writes: My maternal grandparents had a large family of sons and daughters, and on Sunday mornings the old lady assembled her daughters, and gave to each a glassful of lime water. In rotation each had to swallow the dose, while the boys, as if of a different order of beings, escaped. I do not know that the custom was widespread, but that it existed may be of interest in view of recent investigations into the relationship between menstruation and calcium metabolism.

SOUTHWOLD LIEB CASE.

THE following additional subscriptions have been received by the fund opened to assist Drs. Mullock and Tripp in defraying the heavy expenses which they incurred as the result of the recent action which they were called upon to defend:

	£	s.	d.
Dr. E. S. Moorhead, Winnipeg, Canada	5	5	0
Anonymous, Suffolk	2	2	0
Dr. J. Allnutt, Wangford, Suffolk	1	1	0
Dr. S. W. Woollett, Newmarket (late Southwold)	1	1	0
Dr. F. E. Rock, Winchmore Hill, N. ...	1	1	0

Cheques should be made payable to Dr. H. P. Hesham, Beccles, or to Dr. W. Tyson, Lowestoft.

MEDICAL FOOTBALL.

By twenty-one points, or by seven tries to nothing, Guy's Hospital defeated Middlesex in the final round of the Cup Tie, played last Tuesday at Richmond.

Despite the fact that the result was looked upon as a certain win for Guy's, there was a very fair attendance, and during the first half-hour of play the supporters of the Middlesex had the satisfaction of seeing the hospital hold its own against Guy's with complete success. After about twenty minutes of play, however, Gabe had to retire owing to an injured shoulder, and Harrison was brought out of the "scrum" to take his place in the three-quarter line. For ten minutes longer the Middlesex defence held, but at last they gave way to pressure, and as a result of some clever play between Sauer and Medlock, Lee succeeded in slipping over the line. A second try followed almost immediately, Stokes touching down. As before, he took the kick, but failed to convert. When half-time was called Guy's led by two tries to nothing, and the most interesting features of the game had been the excellent defence of the Middlesex backs, contrasting with the brilliant attacking qualities of their rivals. Even in this half the Guy's forwards showed their superiority, getting the ball in nearly every "scrum," and heeling it out to their backs. The Middlesex pack were only able to shine occasionally in the open, scoring several advantages by individually clever work.

The interval at half-time encouraged Guy's, but completely disorganized the Middlesex, who, it must be remembered, were playing with a man short. Almost immediately after play was resumed, Guy's pressed their opponents, their opportunity being due to the treacherous greediness of the turf. One of the backs fell, and there was a "scrum" almost on the Middlesex line, only relieved after a bout of keen forward play by Penny, who took the ball across the ground. The first score of the second half was due to a clever bit of individual play by Williams, who successfully passed the line. After the resumption of play, Middlesex, for the only time in the game, seriously took the offensive, and, circumventing Guy's, kept them hard at work defending within their twenty-five. The situation called for heroic measures. Stringer and Jones combined, took the ball up the field, gave Stokes his opportunity, and enabled him to score. Stokes failed to convert, despite the fact that there was no wind, this being the fourth attempt. For the rest of the game the Middlesex remained on the defensive, and the interest of the match centred in a debate among the lookers-on as to how many tries the winning hospital would have to score before they would be able to convert a single one of them. The game failed to answer the question, though a seventh try was scored before time was given. For the losing side, Penny was the most conspicuous, and to him Middlesex owed the flashes of brilliant play that mitigated their defeat. The winners owed most to Lee and Jones, who gave a capital display of unselfish combination. Sauer and Medlock, at half, proved extremely effective, and Stringer was very conspicuous. Medley did well as full back.

Including the result of Tuesday's match, Guy's have held the Inter-Hospital Cup twelve times, St. Thomas's once next to them with ten wins. The number of wins to the credit of the other hospitals are: London, five; St. George's, three; St. Bartholomew's, two; and St. Mary's, one. In 1890-1 the competition was unfinished.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 529, Strand, London, not later than the first post on Wednesday morning preceding publication; and, if not paid for at the time, should be accompanied by a reference.

N.B.—It is against the rules of the Post Office to receive letters at Postes Restantes addressed either in initials or numbers.

An Address

ON THE

NATURAL HISTORY OF ULCERATIVE COLITIS AND ITS BEARING ON TREATMENT.*

By HERBERT P. HAWKINS, M.D., F.R.C.P.,

PHYSICIAN TO ST. THOMAS'S HOSPITAL.

THE proved value of serum treatment in tropical bacillary dysentery makes it important that the active bacterial agents in ulcerative colitis should be known. It is the very type of disease which should yield to serum or vaccine treatment. The site of infection is localized, there is no general infection, and the symptoms are mainly local and exhaustive, though partly toxæmic. If it is not cured in an early stage, nothing remains as a rule but such crude measures as colostomy and ileo-sigmoidostomy. The necessity for bacterial treatment holds good, whether the primary organism concerned should ultimately prove to belong to the dysenteric, paratyphoid, *coli* or pyogenic group. Nothing can be done until the natural history of the disease is understood.

The pedigree of the disease can be traced back for nearly 300 years. It was then called dysentery, or bloody flux. In the seventeenth century epidemics were common in this country. There were sometimes 4,000 deaths a year from "bloody flux." These epidemics usually occurred in the fly season, but sporadic cases were met with also in the spring and winter. In the eighteenth century, probably through a safer disposal of excreta, epidemics became less common. In the nineteenth century they nearly disappeared in the open, except in Ireland, but they persisted in certain institutions, Millbank Penitentiary and various asylums being the chief offenders.

At the present time small outbreaks still occur in asylums. They still occur also on a small scale in the open, and the evidence is almost conclusive that both in these small epidemics and in asylum outbreaks the disease is spread by direct transference of infected material from person to person. Thus a small epidemic (Carver) arose in and around the Great Northern Central Hospital, in which children and adults were equally infected. In 1900 a small outbreak (Cantley) occurred in a London barracks. On one staircase lived 15 women and 30 children. Of the adults, 3 were infected and recovered; of the children, 6 were infected and 4 died. Both these outbreaks occurred in the fly season. In August and September of 1901 an epidemic occurred at Aldershot, and of the civilian population between 170 and 180 persons were attacked, of whom 38 died. All ages were affected, but of the 38 deaths 28 occurred under the age of 5, and 3 over the age of 65. This mortality-rate of about 27 per cent. is identical with that of Japanese dysentery before serum treatment was adopted. The reporting medical officer of health states that flies were very numerous at this time.

This same decline of the epidemic and persistence of the sporadic disease are to be noted all over Europe, except in the south-eastern fringe, where epidemics still occur. The sporadic case is still with us, just as Sydenham described it, and it has never altered its form. His description of the disease in 1669 may be applied word for word to the condition as we now see it. One sentence may be quoted, because I believe that a non-necrotic "dysenteric diarrhoea," such as he alludes to, is still to be recognized: "With these slimy motions appear streaks of blood, though not always; sometimes, indeed, there is no passage of blood whatever from first to last. Notwithstanding, provided that the motions be frequent, slimy, and attended with griping, the disease is a true bloody flux or dysentery." Though a few cases of dysentery are specified in the Registrar-General's report, this separate heading has only appeared in the last few years, and the bulk of our cases are probably buried with the 20,000 annual deaths from diarrhoea.

When the epidemic disease became insignificant, the sporadic case ceased to attract much attention, and it eventually acquired the new name of "ulcerative colitis." For the moment I think this is a better name than

"dysentery," and there should be no reversion to the original name, unless and until it has been shown bacteriologically that this disease belongs to the dysenteric group.

THE CLINICAL EVIDENCE.

This disease comes before us in varying guise, as a short severe illness, and as a long illness continuous or intermittent. To these three forms I think must be added a simple non-necrotic diarrhoea, often the precursor of a more severe attack. The difference between these various forms is not a matter of symptoms and physical signs. These are constant. The difference rests mainly on the duration of illness and partly on the mode of onset, and in both these respects this disease presents greater variation than does bacillary dysentery.

In considering a series of 85 cases (for about three-fourths of which I am indebted to my colleagues at St. Thomas's Hospital) one question is kept in view—namely, Are all these cases of the same nature, or are different diseases mixed under one name?

If an answer to this question can be given it will allow a definite though weak presumption, that an organism known to be causal in one case is the cause of all the others, and an attempt at appropriate treatment will follow. At the same time, the subsidiary question may be considered as to how far all or any of these cases resemble or differ from the bacillary dysentery of tropical countries. In all these 85 cases the disease was acquired in this country.

A.—The Acute Continuous Disease.

Among these 85 cases (of whom 41 died and 44 survived) we find instances both among the deaths and the survivals which, to my mind, so far as symptoms go, are identical with bacillary dysentery. I think, if the following cases occurred in a tropical country, no one would think twice about the diagnosis.

CASE I.

Man aged 59. Sudden onset of diarrhoea, with cramp in legs, and abdominal pain, mostly in right iliac fossa. Vomited three times. Stools five to six a day, much blood and mucus. Slight fever, 99.1° F. Hiccough. Tongue became red, glazed, and dry. Pulse 132, falling rapidly. Death on twenty-third day. *Post-mortem*: Colon ulcerated from end to end; ulcers ovoid with swollen rounded edges, separated by strands of sodden mucosa, sometimes confluent over large tracts, mostly extending down to muscular coats, a few to peritoneum. No disease elsewhere. From splenic blood, after death *Bacillus coli* and *Bacillus proteus* grown.

CASE II.

Woman aged 31. No previous attack. Sudden onset of rectal pain and passage of blood. Continuance of hæmorrhage and profuse offensive discharge, with little faecal matter. Slight fever. Death on thirty-eighth day. *Post-mortem*: Ulceration of whole colon and rectum; in caecum only a few polypoid islets of mucosa remained; no disease elsewhere.

Two similar cases ending in recovery may be quoted, in one of which the serum agglutinated Shiga's bacillus.

CASE III.

Man aged 25. No previous attack. Onset of diarrhoea slight at first, then more severe with abdominal pain; stools five to six a day, offensive, slimy, with streaks and clots of blood; genuine tenesmus; fever for one week. Treated with bismuth and Dover's powder. Apparently complete recovery; duration about six weeks. Subsequent history unknown.

CASE IV.

Woman aged 41. Sudden diarrhoea; stools every fifteen minutes at first, with straining and genuine tenesmus and pain on defaecation, most stools containing red blood. Tongue red and dry. Temperature normal. Treated with bismuth and opium and creolin irrigation; quickly improved, and was discharged apparently cured on the fortieth day of illness. Subsequent history unknown. Her serum id in 100 agglutinated Shiga's bacillus at once. It is highly probable that this was a case of bacillary dysentery. It is noteworthy (cp. later evidence as regards dysenteric diarrhoea) that she stated that she had a similar but slighter attack three months previously and recovered completely.

Out of this series of 85 cases, 20 may be described as being of this "short, continuous type," which so closely resembles bacillary dysentery. A picture of the condition in the British case comprises a sudden onset, sometimes with constitutional disturbance, diarrhoea (up to twenty or more stools a day), the passage of mucus and blood, the blood being red, in considerable quantity, or

mixed with inflammatory exudation to form reddish-brown or black liquid stools, severe gripping pain in connexion with defaecation, and in some cases true rectal pain and tenesmus, fever in nearly 50 per cent, and signs of toxæmia in the severe cases, dry tongue, parching of mouth, and rapid wasting.

B.—The Chronic Disease, Continuous and Intermittent.

As regards the remaining 65 cases, I think it may be said with truth that in all of them there occurred at one time or another a phase of the illness, during which phase this same close resemblance to bacillary dysentery was maintained. But it was a phase only (sometimes an opening, often a terminal scene), and if this phase is put on one side, it must be confessed that in their general course these 65 cases bear little resemblance to the acute cases already described and to the majority of cases seen in tropical countries. The mere duration of the illness might lead one at first sight to think that we are dealing with some disease which is met with only in temperate climates. If we look at a rough table of duration we see something in chronicity of disease that is rarely, if ever, met with in the tropics.

In 30 of these 65 cases the illness was continuous from first to last, with little or no tendency to intermission or improvement. In 15 of these (fatal cases) death occurred:

In the third month...	...	in 3 cases
In three to six months	...	in 2 "
In six to eight months	...	in 2 "
In eight to ten months	...	in 2 "
In ten to twelve months	...	in 2 "
In eighteenth month	...	in 1 "
In two to two and a quarter years	...	in 3 "

In the 15 patients who left hospital alive only the minimum duration of illness can be given, because though they survived it is doubtful if many can be said to have reached a cure. The duration was:

Two to six months...	...	in 3 cases
Seven to twelve months	...	in 4 "
One to one and a half years...	...	in 3 "
Nearly two years	...	in 1 "
About three years	...	in 2 "
Five to six years	...	in 2 "

But this wide departure from the usual type of bacillary dysentery becomes wider still when we consider the remaining 35 patients. In these the story is often of immense duration. These cases must be described as "intermittent" or "relapsing," or as "comprising a series of separate attacks" with a decided tendency to cure, but always falling short of a complete cure. Of these 35 patients, 11 who did contributed a history of twenty-one attacks of diarrhoea, generally (cp. Sydenham's description) but not always associated with the passage of blood previous to the final and fatal attack which brought them into hospital. The 24 who survived gave similar histories of great duration. Thus 18 contributed a history of thirty-seven previous attacks, 5 gave a history of "several" previous attacks, and 1 stated, I believe with truth, that she had had an attack nearly every August for sixteen years.

C.—Dysenteric Diarrhoea.

Thus we have the concept of a long, intermittent diarrhoeal disease running over many years (eighteen years in one case, over five years in many cases), and probably these 35 patients may be fairly stated to have had seventy or eighty previous attacks of diarrhoea between them. As a rule, these early attacks are less severe (cp. Cases v and xiii), and severity increases with recurrence. It is probable that in some of them there is no actual ulceration. They are analogous to slight cases of bacillary dysentery which proceed no further than a superficial catarrhal inflammation. If they are reckoned, as I think they should be, as part of the unit "ulcerative colitis," then this disease becomes much more common than is generally supposed. I think that any case of sudden violent diarrhoea in this country that runs into a second or third day, especially if there is no sign of affection of stomach or small intestine, should be regarded with suspicion, and if blood and mucus are passed I think the case must be put into this group.

An example of this recurring disease may be given

which shows how far we have travelled from the usual picture of a bacillary dysentery as seen in tropical countries. It shows also how the early attacks of dysenteric diarrhoea which often precede a final severe attack may be regarded lightly, and how a cure may be recorded under any kind of haphazard treatment which much later events may disprove.

CASE V.

Governess, aged 34, liable to diarrhoea (that is, several slight attacks) for eighteen months. Last attack was longer and more severe, she passed blood and mucus, had considerable abdominal pain, and was admitted into hospital in April, 1896. In two months she seemed to be cured, and she was discharged in June. She remained well till September, when the same symptoms returned, and she was again admitted in October. After one month of treatment she seemed to be well again, and she remained well till April, 1897, when the symptoms returned, hæmorrhage being severe, and she was readmitted in May. Treatment now had little effect, and in September left colostomy was performed without benefit. In January, 1898, ileo-sigmoidostomy was performed with success, but in April an attempt was made to close the colostomy wound, and she died three days later from general peritonitis. *Post mortem* there were found a large ulcer in the long axis of the splenic flexure, and a similar ulcer in the iliac colon, with some patches of grey scar tissue around it. No disease of colon past or present, above the splenic flexure. The total duration of illness was two years.

In another patient of this class who recovered, for a time at any rate, Shiga's bacillus was agglutinated.

CASE VI.

Man aged 31. Four years ago had several short attacks of abdominal pain, vomiting, and diarrhoea, sometimes with passage of blood. Then occurred an interval of three years of good health. In February, 1906, another severe attack, stools four to five a day, occasional blood, much mucus, great loss of weight, no fever, occasionally sick. He apparently recovered completely in three months, but the subsequent history is unknown. Shiga's bacillus was agglutinated by his serum, dilution 1 in 20 giving good diffuse clumping in one hour, 1 in 50 slight clumping in one hour, 1 in 100 no reaction.

D.—The Acute and the Chronic Disease.

We have now before us, then, the single attack proving fatal in three to six weeks, and the long continuous or recurring illness (or series of attacks) often tending to increase in severity, and spread over two to eighteen years. Are the short attack and the long illness separate forms of disease, or is this wide illness a single unit with great variation in duration?

To my mind the evidence, so far as clinical study can go, is in favour of unity. Between the temporary diarrhoea with or without bleeding, the short fatal illness, and the long recurring illness, clinical evidence shows no differentiating feature except the mere duration. They cannot be separated into two or more groups. There is a perfect gradation from the illness of thirty days to the long illness of many years, and there is no break. At any time in the long illness, as will be shown, there may supervene an acute attack which may rapidly prove fatal. The early attacks in the long cases are often severe enough in themselves. They differ in no particular from the short single attack which proves fatal except in their lesser severity, and in any one of them with a little less luck the patient might have died, and so have converted a potential long illness into an actual short fatal attack (cp. Case xiii).

If it is granted that we are dealing with a single unit, how does it compare with tropical bacillary dysentery? Is there anything in tropical countries which resembles our long-continued home-grown disease? It is clear that such a long-continued illness is at any rate not very prominent in the minds of experienced writers on tropical dysentery, but it is present. Of Japanese dysentery Shiga states that the duration is four to eight days in the light cases, and three to six weeks in the serious ones, and that in fatal cases death usually occurs in two to three weeks. But he adds, without any details, that the disease may become chronic, with a tendency to relapse, and he speaks of this as "a subsequent disease in which we cannot find the dysenteric bacillus." Davidson describes chronic dysentery as being a direct persistence of an acute attack, or a persistence by relapse, or a chronic disease from the first. As regards the ending of such a case, he says that "the patient after months or years of suffering dies of exhaustion or is carried off by some intercurrent disease."

I think we may take it, therefore, that the great variation in duration of the British disease is not without parallel in the experience of the tropics. There remains, however, the striking difference between the United Kingdom and tropical countries as regards the relative proportional frequency of the short case and the long case; the latter bulk largely with us. I expect they form 70 to 80 per cent. of our cases. In the tropics they form a small minority. But they may be more common than is generally supposed. As a matter of fact we often see such cases returned from the East, and they present just the same difficulties with regard to treatment, medical and surgical, as our native product.

Two examples of long-continued tropical dysentery for comparison with the British disease may be given:

CASE VII.

Soldier, aged 30. Went to India in 1895; dysentery there in 1898. For next four years liable to attacks of diarrhoea. In 1902 to South Africa, where second severe attack occurred. Liable to diarrhoea since. In December, 1904, having left the army and become a meat-porter in the Old Kent Road, he had a third severe attack, stools hourly, mucus and blood passed, tenesmus, prolapse of rectum, abdominal pain during and after defecation. Improved considerably, but in February, 1905, a fourth severe attack occurred, which continued off and on, till April, 1905, when he was admitted into hospital. He had lost 5 st. in weight in four months. Ulceration of rectum could be seen with speculum. Stools now two to four a day, containing abundance of polymorphonuclear leucocytes and generally visible blood. No amoebae found. Temperature normal. Under medicinal treatment and irrigation he improved considerably, regained a little weight, and left on June 23rd to resume work. Subsequent history unknown. Reckoning from the start (as with our British cases), the duration up to date is about seven years. He was certainly not cured when he left hospital.

CASE VIII.

Man aged 38. In 1898 he had his first attack of dysentery on board ship off the East Coast of Africa. In succeeding years in this country he had slight recurrences. In 1905 he had another severe attack in Rhodesia, and he has been liable to diarrhoea ever since, with passage of blood and severe griping. In April, 1906, he was admitted into hospital. A culture from stools yielded only *Bacillus coli* and an atypical bacillus of this group. With medical treatment and twelve injections of *Bacillus coli* serum he improved considerably, and left in August. Three weeks after discharge he was as bad as before, with constant pain and haemorrhage. He returned to hospital, and a right colostomy was performed. A period of comparative peace ensued, though a blood-stained discharge from rectum continued until August, 1907. A course of irrigation with silver nitrate was then tried; it was badly borne and proved useless. Two unsuccessful attempts at ileo-sigmoidostomy were made in 1908. There can be no doubt that at this date, ten years after the first attack of dysentery, the colon is still ulcerated.

E.—The Haemorrhagic Disease (Lower Segment Type).

From a study of the mode of onset a point is extracted, which is more likely to have a differentiating significance than the mere duration of the case. In 10 of these cases simple bleeding from the colon preceded the diarrhoea and all other signs of colitis. Of these 10 patients 6 died and 4 survived, though I doubt if they were cured. In 2 of the fatal cases there was actual constipation with the haemorrhage, so that aperients were necessary. In 2 cases haemorrhage continued off and on for about eighteen months, in another case for twelve months, and in the others for days, weeks, or a few months before diarrhoea began. In all of them, however, diarrhoea and all the symptoms with which one is familiar in the more usual form of ulcerative colitis, set in sooner or later, and the condition of the colon after death did not differ from that found in the patients who began their illness in the more orthodox diarrhoeic way.

I know nothing of such a stealthy haemorrhagic mode of onset in tropical dysentery, but I suppose it is possible that both this unorthodox beginning and also the large relative proportion of chronic cases as compared with acute cases in this country can be explained in the same way up to a certain point. The severity of the disease and the degree of toxæmia vary with the site of disease in the bowel. This is clearly the case in bacillary dysentery. Shiga speaks of an "ascending" and a "descending" dysentery. In the majority of tropical cases the disease begins in the rectum and iliac colon, and remains localized there or ascends thence. In a small proportion it begins in the caecum and descends. This latter form presents the more severe results, and a still graver intoxication ensues when the lower end of the ileum is also affected,

and the disease then as regards toxæmic symptoms may approximate to enteric fever. The higher the site of disease, the more severe and general are the symptoms; with a lower site they are milder, and the results are more local.

There is evidence to show that this variation in the site of the disease, with a corresponding variation in the severity of the symptoms, occurs in British ulcerative colitis as in tropical dysentery. In Case v a relapsing illness of two years occurred, but the patient was never gravely ill, and might have recovered. Post-mortem examination showed that the disease had never extended upwards above the splenic flexure. It was a lower segment disease from first to last, there was no great toxæmia, and death was accidental.

This may be contrasted with Case i, in which the disease was of the upper segment type, "pain in the caecal region" was the earliest symptom, the illness was grave from the first, intoxication was severe, and death took place on the twenty-third day.

Far apart as these two cases seem, I see no reason for thinking that they are not of the same nature, considering that in Japanese dysentery, a disease of known uniform causation, there is noted the same variation of severity with the segment of colon affected. If in Japanese dysentery, as is frequently the case, the infection remains limited to the rectum and lower colon, the symptoms are mild and the prognosis is favourable. The following three cases may be interpreted as examples of long continuance of lower segment infection with preservation of fair health, followed by sudden rapid extension to the upper segment ending in death:

CASE IX.

Woman aged 37. In 1902 she began to pass blood and slime with loose stools. The haemorrhage persisted with loose but not frequent stools, and in January, 1903, she was admitted into hospital. So local did the disease seem to be, that a shallow abrasion just above the sphincter was cauterized and an ulcer 2½ in. from sphincter on posterior rectal wall was excised. In March, 1903, she was again admitted for fissure in ano. All through this year and for six months of 1904 she continued to pass blood and mucus from time to time, but was never laid up. In the autumn of 1904, that is, at least eighteen months after the first appearance of blood in the stools, a sudden change occurred. Diarrhoea set in with considerable abdominal pain. She wasted rapidly. Stools up to sixteen a day. Slight fever. Colostomy was performed in November, 1904, irrigation employed, and she improved considerably. Pain and diarrhoea ceased, but as usual in such cases blood and mucus were attempted to perform ileo-sigmoidostomy resulted in fatal peritonitis. Post-mortem the colon was found to be uniformly ulcerated from end to end. I think it is probable that up to the autumn of 1904 her infection was limited to rectum and pelvic colon.

CASE X.

A solicitor's clerk, aged 22. Had never been out of England, and had had no previous illness. In 1902 a brother was invalided home from South Africa convalescing from enteric fever. Soon after his arrival this patient acquired enteric fever. He made a good recovery, but stated that he always had some trouble with his bowels afterwards, an irregularity with constipation predominating, and the passage of mucus. This may or may not have any connection with the subsequent illness. About a year later this became more marked, and he began to pass small quantities of dark blood in most stools. This bleeding continued from December, 1904, to May, 1906, but during these eighteen months his general health remained good, there was no pain or diarrhoea, aperients were often necessary, and he actually continued at work, though his weight gradually fell from 10½ st. to 8 st. On May 11th, in this case, I see two parts—(1) eighteen months of lower segment disease and haemorrhage; (2) six weeks of disease of upper colon not to be distinguished from tropical bacillary dysentery.

CASE XI.

A lady, between 50 and 60 years of age, noticed blood in her motions in May, 1890, but she had no pain or diarrhoea. This haemorrhage soon ceased, and she seemed to be quite well. In the following October, however, diarrhoea and abdominal pain set in. The diarrhoea was severe, over twenty stools a day being noted, a good deal of blood was passed, and there was great tenesmus. She died five or six weeks later. The colon was ulcerated from end to end, and the underlining was very

marked, some ulcers being spanned by bridges of surviving mucosa.

CONCLUSIONS.

I think (1) that the great variation in the duration of the illness, and the fact that in some few cases simple colic haemorrhage may for a long time be the only sign of disease, do not necessarily require that we should regard these cases as separate forms of disease, distinct from the dysenteric diarrhoea and from the short fatal illness, which so closely resembles bacillary dysentery, and (2) that both points may be explained on the ground of primary localization in the lower segment of the colon.

THE BACTERIOLOGICAL EVIDENCE.

From the clinician's point of view tropical bacillary dysentery is a unit of disease. So it will remain. It presents some differences as regards degree of toxæmia and duration, but these differences are small as compared with those noted in the British disease. Bacteriology, however, shows that it comprises several groups, each of which is dependent on a definite specific organism separable by agglutination and by sugar-fermenting reactions. Probably there are three or four such groups. The two varieties of Shiga and Flexner certainly account for the dysentery of Japan, China, the Philippines, and the West Indies. One or other of these varieties has been so often isolated from cases of dysentery and even of non-necrotic diarrhoea in temperate climates—for example, America (Flexner), Germany (Kruse), France, Austria, and Holland—that its general causal connexion is highly probable. But it must be noted that these observations have been mostly made in institutional epidemics, and not on the sporadic cases which we are considering. *B. dysenteriae* has, however, been found in sporadic cases in Philadelphia.

The range of *B. dysenteriae* has been recently extended. It seems to be proved that the ubiquitous Shiga and Flexner varieties are the chief cause of the diarrhoea of children in New York, both in summer and winter, the Flexner variety predominating, both varieties sometimes co-existing. To this pair Hiss and Russell added a third, which differs from Shiga's bacillus only in fermenting mannite. A fourth variety, such as was found in children by Wollstein, must be recognized, which ferments saccharose, maltose, and dextrin. Shiga tentatively adds a fifth variety.

Now it may be taken as highly probable that the small epidemics which still occur in asylums in this country are also dependent on *B. dysenteriae*. Eyre found Shiga's bacillus in 6 out of 10 cases. McWooney isolated Flexner's bacillus from 1 case. Boycott found Flexner's bacillus in 17 out of 19 cases. But investigation of our sporadic cases hangs fire and is inconclusive. From 1 case only, so far as I know (acute case of a child), has Flexner's bacillus been isolated in this country (Marshall). Sandby has reported 2 cases from which Hewetson is said to have obtained Shiga's bacillus, but as regards the first of these the identity must be disallowed.

Sporadic disease is more difficult to investigate than an epidemic. Cases commonly reach the chronic stage before examination is possible. Even in the acute asylum cases it is seen that the specific bacillus was not isolated from every case examined. Eyre states from his further observations that in cases of chronic asylum dysentery (which probably corresponds to the bulk of our sporadic cases) *B. dysenteriae*, if present, is so outnumbered by *B. coli* and other intestinal saprophytes as to render its isolation a matter of extreme difficulty.

Further, we have Flexner's observation that even in tropical bacillary dysentery the faeces do not contain *B. dysenteriae* in such numbers as to make it possible to recover them as readily as from the intestinal mucosa, and that a scraping from the rectal mucosa will yield *B. dysenteriae* when it has not been found in the faeces. This is confirmed on all sides. Once outside the crypts and substance of the mucosa, it is quickly overgrown by saprophytes.

Consequently the following results of examination of "faeces" in ulcerative colitis at St. Thomas's Hospital are of little or no value. In 6 chronic cases *B. coli* was thus obtained: Pure in 2 cases, with *B. proteus* in 2 cases, with *Streptococcus faecalis* in 1 case, with this organism and *B. pyocyaneus* in 1 case. In 4 other cases the stools were examined for *B. dysenteriae* with a negative result.

Now as regards scrapings from the intestinal mucosa, Dr. L. S. Dudgeon has kindly examined 2 cases for me.

CASE XII.

Man aged 34. In May, 1908, began to pass blood, with a continual ache about the sacrum. A week later diarrhoea set in, five or six stools a day, generally containing blood, with griping, fever, and loss of weight. He lost ground until November, when improvement began. In January, 1909, he had regained 14 st. in weight, and was passing one or two fairly well-formed stools daily without blood. Though he appeared to be convalescent, I doubt if he was cured, and his rectum remained very red and moist, and it bled unnaturally on gentle scraping. Broth was inoculated with the scraping, and after four hours' incubation this was plated on Drigalski's and Conrad's media and on MacConkey's lactose agar. *B. coli* was found on all plates. But the blue colonies on the former media and the white colonies on the latter consisted of bacilli which gave almost identical reactions. This bacillus was slightly but distinctly motile when emulsified in normal saline; it was agglutinated, dilution 1 in 20, in thirty minutes at room temperature by the patient's serum, but there was no reaction with dilution 1 in 50. It was Gram-negative. It fermented, with production of gas, glucose, maltose, mannite, glycerine, salicin. It did not ferment lactose, raffinose, cane-sugar, or dulcitol. No action on neutral red broth. Litmus-milk alkaline; no clot after several days. Peptone, no indol. Jelly, no liquefaction. Other colonies examined gave similar results, except that salicin was unaffected. In two rabbits inoculated intravenously and in two guinea-pigs inoculated intraperitoneally no results followed. This patient's serum did not agglutinate either standard typical Shiga's bacillus or the bacillus obtained from the next case, or *B. typhosus*.

CASE XIII.

Man aged 23. In June, 1903, he had his first attack. Sudden onset of violent diarrhoea, stools up to ten a day, some containing bright red blood, much slime, severe griping across lower abdomen. Under treatment this subsided; in three weeks he was beginning to improve, and in six weeks he was apparently well again, and his stools became normal and formed. In tropical countries this would have been called dysentery, but no bacteriological examination was made. On December 11th a second attack of the same kind began. Profuse diarrhoea, with blood and mucus, great rectal pain as well as general griping, vomiting, fever. This soon proved to be more severe than the first attack, and he began to lose weight. In January, 1909, his rectum was very red, granular, and moist, and it bled on the least touch. A high scraping was plated direct on to MacConkey's lactose agar gave the following results: The majority of colonies after twenty-four hours on two plates were white, the remainder red. These latter were true typical *B. coli*. The white colonies consisted of a bacillus, Gram-negative, non-motile. This bacillus fermented with production of gas, glucose, maltose, glycerine, mannite, and cane-sugar. It did not ferment lactose-broth (but formed acid and gas in lactose-jelly at 22° C.), salicin, raffinose, inulin, or dulcitol. No action on neutral red broth. Litmus-milk, very slight acidity, no clot, result permanent. With peptone, indol; jelly, no liquefaction. Patient's serum did not agglutinate either this bacillus, diluted 1 in 10, 1 in 50, or Shiga's bacillus. This bacillus was not agglutinated by serum of the preceding case.

In the next fortnight the patient went rapidly downhill, with great wasting, severe pain, raw tongue with aphthae, and parched throat. Right colostomy was therefore performed. A scraping made from the caecum and plated direct on to Drigalski's and Conrad's media and MacConkey's lactose agar, gave only *B. coli*, abundant growth of *B. pyocyaneus*, and *B. proteus*. In spite of the diversion of faeces and irrigation the patient died nine weeks after the commencement of his second attack. Only a small part of the colon could be obtained for examination—namely, the transverse colon and splenic flexure. Over the whole of this the muscular layer was exposed, only a few polypoid fragments of mucus and sub-mucous layers remaining. Such a fragment showed (1) infiltration of mucosa and submucosa, and to a less extent of the outer coats, with small and large mononuclear cells, some plasma cells, a few eosinophiles, no polymuclear cells or basophiles; (2) thrombosis of capillaries and small vessels; (3) haemorrhagic oedema of muscular coats; and (4) bacilli, short and fat, long and thin, throughout the whole intestinal wall, an infective condition which accounts for the toxæmia and the failure of treatment. Such a fragment was secured and incised, and a scraping was plated direct on to MacConkey's lactose agar. Here again *B. pyocyaneus* and *B. coli* were obtained. But the predominant growth was a white colony consisting of bacilli, having much the same characters as the organisms grown previously from this patient's rectum and from Case XII. Two such white colonies worked out gave nearly the same results. It was a short, Gram-negative bacillus, non-motile in one case on agar jelly, in the other case non-motile on agar but slightly motile on jelly. They gave no reaction with antidyenteric serum (Shiga). They fermented with production of gas, dextrose, mannite, maltose, cane-sugar, lactose, and dulcitol. They did not ferment inulin or raffinose. They had no effect on neutral red broth and did not liquefy jelly. They both produced indol. With litmus milk one produced acidity with slight clot after several days, with the other milk remained alkaline for five days and was then decolorized.

Turning now to the agglutination reaction, we find some evidence in favour of the identity of ulcerative colitis with bacillary dysentery. Foulerton obtained the reaction with Flexner's bacillus in 3 cases, dilution 1 in 40, 1 in 100. Vedder and Duval record the same results with Shiga's bacillus. Vaillard and Dopter found the reaction well marked, diluted from 1 in 20 to 1 in 300, in an outbreak at Vincennes. Hewlett obtained a positive reaction, with Flexner's bacillus in 2 cases of asylum dysentery. In Boycott's cases a reaction with Flexner's bacillus was noted, sometimes with dilution up to 1 in 200 and 1 in 500, but Shiga's bacillus was unaffected. A multivalent anti-dysenteric serum agglutinated the bacilli, which he isolated, with a dilution of 1 in 1,000, and when so examined even 1 in 10,000. The Shiga's bacillus obtained by Eyre was immediately agglutinated by anti-dysenteric (Shiga) serum with dilution 1 in 200, and by the serum of another patient in similar dilution. In a woman under my care (Case iv) Shiga's bacillus was immediately agglutinated by her serum. In Case vi also the reaction was obtained, though in less dilution. In 5 of our chronic cases, on the other hand, there was no reaction with Shiga's bacillus, though Flexner's bacillus was not tested.

The agglutination test, therefore, leaves us in the same doubt as does the search for a specific bacillus. The case is nearly conclusive for asylum dysentery, it is suspicious for the acute sporadic case, and it fails entirely against our common chronic disease. Yet I think the clinical evidence must be taken to mean that our long-continued case is directly related in some way to our short fatal illness, and perhaps also to the acute asylum case. In such an instance as Case xiii, where the patient tided through a short severe attack of three weeks, only to relapse three months later and die after a second illness of nine weeks, we must conclude that both illnesses were of the same nature. This instance is only one of many. Now it may be taken as nearly certain that *B. dysenteriae* was not present in this second attack, or at any rate during the last five weeks of it. Was it present in the first attack or in the first four weeks of the second attack?

If the clinical evidence is considered to be strong enough to warrant the belief that the short illness and the long illness own the same origin (perhaps one of the organisms of the dysenteric group), it is possible that the relation between them may be explained on the hypothesis of a concurrent or consecutive action of organisms of the paratyphoid or *coli* variety, or of pyogenic cocci. *B. pyogenes*, also, may be an important factor. In the analogous intestinal infection of typhoid fever there is considerable evidence indicating concomitant failure of the normal intestinal protection against *B. coli* and pyogenic cocci. It is known that from tropical bacillary dysentery in a chronic stage *B. dysenteriae* can no longer be obtained, and, in such examples of tropical disease as Cases vii and viii, one can hardly doubt that the perpetuation of the disease is the work of common non-specific organisms. It may be that the chronic British disease is similarly a secondary non-specific ulceration, in which case the prospect of a generally applicable specific treatment becomes remote.

TREATMENT.

Of these 85 patients 41 died. Of the 44 survivors, many improved, but I doubt if more than 8 of them were cured. These figures, being drawn from hospital and consulting work, naturally only include the severe and chronic cases. In all the fatal cases the colon was examined after death, and in all these, except one (Case xvi) the colon was extensively ulcerated, such ulceration not being due to typhoid fever, tuberculosis, or other recognized cause.

Until specific treatment can be provided I do not think any dogmatic rules of treatment can be produced. I have nothing useful to say; but, looking back on the cases for which I have been responsible, I feel sure that lives might have been saved by an earlier recourse to colostomy. As regards serum treatment, there is no doubt that immune serum has a specific agglutinating action on each member of the dysenteric group. Vaillard and Dopter, however, find that serum immunized with the Shiga-Kruse bacillus has a favourable influence on cases, whether they are due to Shiga's bacillus or to Flexner's bacillus. Shiga has made a serum covering three types. The Shiga-Kruse bacillus

alone is used by the Lister Institute for the manufacture of their serum. In France, Coyne and Auché have made a Shiga-Flexner serum, which is effective in infantile colitis.

I have used the serum of the Lister Institute freely in 5 cases, but I can offer no opinion as to its utility, for all the cases were chronic and various other methods of treatment were in force at the same time. The *coli* serum used in Case viii seemed to be beneficial. As regards *coli* vaccine, which was used in many cases, no obvious benefit can be noted. Case xiii had three doses of a vaccine of his own bacillus and of *B. coli* without benefit.

From the point of view of treatment, two classes may be considered.

(1) Dysenteric Diarrhoea.

A short, mild attack may yield to opium and bismuth, but in using these and such-like drugs we are only treating a symptom, and are relying on a natural resistance to the infection, which may or may not be forthcoming. It is clear that ipecacuanha has no specific influence on the disease. As regards Japanese dysentery, Shiga says of ipecacuanha that "it has a very poor place as a dysenteric remedy." In asylum dysentery, also, it appears to be useless. The general custom now is to use calomel, and I believe this to be the best line of treatment. Shiga gives 8 to 12 grains once or twice, or one dose of castor oil 3 to 5 drachms, or one dose of calomel followed by castor oil. In asylum dysentery also Gemmell found calomel beneficial. I prefer to give it in frequent small doses rather than a few heroic doses, and combine it with opium. Calomel, 1 or 2 grains, with opium, $\frac{1}{4}$ grain, can be given three or four times a day.

With the calomel treatment Shiga recommends simple enemata of 1 per cent. saline or soda solution for cleansing purposes (no astringent being permitted), with suppositories of opium, cocaine, or belladonna, and if there is much haemorrhage he applies an icebag to the abdomen and gives opium by the mouth.

Whatever temporary views we hold as to the nature of ulcerative colitis, I believe it is wise to use the serum of the Lister Institute in all acute cases. By its use Shiga states that "the course of the Japanese disease is shortened in those who recover, and lengthened in those who otherwise would die," and his figures show under its use a diminution of the mortality by about one-half (from 22 to 26 per cent., to 9 to 12 per cent.). The serum is bactericidal and antitoxic. I have given as much as 80 c.cm. in a chronic case in which recovery ensued, but it was combined with much other treatment.

(2) Acute and Chronic Necrotic Disease.

In the case which is severe from the first, and in which fever and toxæmia are considerable and widespread inflammation and necrosis of the mucosa are manifested by abundance of polymorphonuclear leucocytes and blood in the stools, the same line of treatment may be adopted. But if improvement is not quickly seen, we are face to face with a condition which may either prove fatal in the next few weeks or may tail off into the chronic and nearly incurable form. The question of local treatment, in addition to the use of serum, becomes imperative. It is easy to be too optimistic and to wait too long for cure. In genuine ulcerative colitis, as distinguished from the great functional and subinflammatory conditions of the colon with which it is often confounded and in which cures under any treatment are common enough, a deceptive appearance of health may be preserved for a time, while the disease extends upwards. Even a pure lower segment infection may quickly get out of control. We have to decide between irrigation per rectum, appendicostomy and irrigation, and colostomy with irrigation and the establishment of a free artificial anus. The right plan can only be settled by the degree of severity of the toxæmia and the probabilities as regards the extent of the disease in each individual case. From what I have seen, I have no high opinion of irrigation per rectum. I think irrigation by appendicostomy has advantages over rectal irrigation, but in no other respect has appendicostomy anything to recommend it. But looking back on many of these cases and on the condition of the colon after death, I believe that colostomy will prove to be the most life-saving proceeding

in the long run. It affords complete rest to the colon as well as efficient irrigation.

The irrigating fluids that may be used are innumerable. Silver nitrate, creolin, boric acid, argyrol, and tannin are often used. Among other things I have tried methylene blue (2 to 3 grains in a pint). In one stationary case under my care, milk, in which lactic acid bacillus had been incubated for twelve hours, was injected daily through an appendicostomy for a long time without obvious result. Similar milk I have given freely by the mouth and in large quantities by rectal irrigation without any apparent benefit. In my most successful case I used an emulsion of sulphur, 120 grains in 4 oz. of oil. This was thrown into the colon through an artificial anus every other day, and on the alternate days thorough sluicing with boric acid solution was carried out. This was employed for seven weeks. With the same idea of using something that will adhere to the mucosa, Shiga has used enemata of gum arabic mixed with bismuth, gallate of bismuth, or iodoform.

That there is some natural tendency to cure is seen from the following case:

CASE XIV.

Man aged 66. In addition to a large number of recent ulcers, large and small, there were several bands and patches of cicatricial tissue, and about these parts the colon was thickened and narrowed. He died on the thirty-fifth day of his illness, but there was a history of previous attacks of diarrhoea. Colostomy was performed, but only just before death, and at too late a period to have induced the healing, and the scars were probably attributable to the earlier attacks.

In two other cases (man aged 34, total duration of illness eight months; woman aged 24, total duration with intermissions five and a half years) the colon showed recent ulcers, healing ulcers, and scars of previous ulcers.

That this tendency to cure is increased by colon-rest is probably shown by the following cases:

CASE XV.

Man aged 39. Total duration of illness was two and a half years. Ileostomy was performed two years, and ileo-sigmoidostomy twenty months, before death. Death occurred from peritonitis arising from an attempt to close the artificial anus. Smooth white patches of scar tissue were found here and there in the colon, with active ulceration in pelvic colon and rectum—that is, below the point of anastomosis.

CASE XVI.

Man aged 34. His illness comprised a series of attacks (diarrhoea and haemorrhage), with intervals of fair health; total duration was two and a half years. Ileostomy was performed twenty months before death, and his death was due to peritonitis arising in an attempt to perform ileo-sigmoidostomy. The whole of the colon was much thickened and irregularly contracted, but no actual scarring could be recognized, and no ulceration was present.

The unpleasantness of an artificial anus can be mastered, and the patient who must use it is by no means a social outcast. The disadvantage lies in the fact that when the colon is out of use it undergoes progressive contraction, and it becomes surrounded by dense fibrous fat. So that after the lapse of a certain time (perhaps a year) both closure of an artificial anus and the performance of ileo-sigmoidostomy become difficult, dangerous, or impossible. A reference to the fatal cases in this series shows this.

In Case VIII, already detailed as an instance of long-standing tropical dysentery, in which colostomy was performed in August, 1906, two separate attempts at ileo-sigmoidostomy were made in 1908. Both proved impossible by reason of the small size of the colon, and its embedding in dense fibrous fat. In fact, at one spot the colon seemed to have no lumen whatever.

While there are these difficulties before us, it is clear that the premature attempt to close an artificial anus before the colon ulceration is completely healed will be equally disastrous. In some extreme cases I believe that the loss of tissue is so deep and extensive that the colon can never be used again, and that either an artificial anus must be used to the end of life or an ileo-sigmoid anastomosis must be established, as to the difficulties of which the instances mentioned above give abundant testimony.

The following case is an instance of such a permanent artificial anus. The case, moreover, is a good example of the lower segment haemorrhagic disease.

CASE XVII.

Schoolboy aged 18. In November, 1903, he noticed a little blood in motions, but there was no pain and no diarrhoea. All through 1904 he passed a little blood from time to time. In December, 1904, there was a sudden extension of infection upwards: he was seized with severe pain, straining and tenesmus, with frequent (hourly at first) passage of liquid stools of blood and mucus. From this time he was confined to bed. During the first six months of 1905 there was almost daily haemorrhage with wasting and profound anaemia. In July, 1905, right colostomy was performed. He gradually improved, simply as a result of the non-use of the colon. Irrigation was tried at times, but never for long and never thoroughly. In January, 1909, he has taken his degree at a university; he can play tennis and bicycle for forty miles, and goes to dances; he looks and feels in perfect health; the artificial anus has acted continuously and well. But twice a day he passes per anum a little blood and mucus, so that we may take it that ulceration is still present even in such a contracted colon as he probably now possesses. By the way it is interesting to note that, in consequence of this complete exclusion of the colon, the ratio of ethereal sulphates to the total sulphates in his urine is as low as 1 to 39.

In another similar case in a woman an artificial anus was established in July, 1906, after one year's illness. In January, 1909, she remains in good health, but washes her colon out daily through the opening.

The matter, however, is not quite so hopeless as would appear from these cases. The following case shows that it is possible to obtain a complete cure by means of an artificial anus:

CASE XVIII.

Woman aged 47. She had had numerous attacks of diarrhoea and bleeding for sixteen years, the attack generally occurring in August and lasting about six weeks. In October, 1907, a similar attack began, but it was more severe, with profuse diarrhoea and great pain. She came under my care in November, 1907. A month of medicinal treatment and rectal irrigation had no effect. In December an efficient artificial anus was established. She received in four doses 50 c.c.m. of antidyenteric serum. After trial of various other irrigating solutions she had 4 oz. of an emulsion of 120 grains of sulphur in oil injected into the caecum every other day, and a free irrigation with boric acid solution on alternate days. After seven weeks of this the result was rather flattering, and the discharge of blood from the rectum and "from the artificial anus" (the ulceration apparently extended up to the caecum) gradually ceased. In April, 1908, with the idea of re-establishing use of the colon, she was given small, steady doses of calomel. When formed stools were produced, in July, the artificial anus was closed successfully. In January, 1909, she remains well. In this case, and in some other equally chronic, I tried the effects of various diets, and I believe that if digestion is good a full mixed diet gives the best result.

In spite of all the efforts of a powerful administration, the law of February 15th, 1902, for the notification of diseases in France has remained almost a dead letter owing to the passive resistance of the medical profession, which shelters itself behind the words of the Act imposing the duty on the medical practitioner of notifying the case as soon as he has "established his diagnosis," words which seem to be thought to leave the obligation so much a matter of discretion, that no serious attempt has been made by the authorities to secure the conviction of practitioners for failing to notify. The objection taken by the medical profession to the law as it at present stands is twofold—first, that it involves a violation of professional secrecy; and, secondly, that the obligation to notify is placed upon the doctor in the first instance instead of primarily upon the father or head of the family, with a secondary liability upon the doctor. The Prime Minister has stated in Parliament that he is quite willing to submit an amending Act in this sense, but only on the condition that the medical profession will "discontinue an abstention which is too general and mischievous to the common good." At present there does not seem much probability of the medical profession taking the initiative suggested by M. Clemenceau.

A CASE OF AMOEBIĆ DYSENTERY WITH ABSCESS OF THE LIVER

IN A PATIENT WHO HAD NEVER BEEN
OUT OF ENGLAND.

[WITH SPECIAL PLATE.]

BY

ROBERT SAUNDBY, AND JAMES MILLER,
M.D., LL.D., F.R.C.P., B.Sc., M.D.Ed., M.R.C.P.Ed.,
SENIOR PHYSICIAN, BIRMINGHAM PATHOLOGIST TO THE
GENERAL HOSPITAL. HOSPITAL.

REPORT OF CASE.

W., aged 42, cycle-rim maker, was admitted into the General Hospital on November 21st, 1908, complaining of pain in the stomach and at the bottom of the back, which had lasted a week. On inquiry from his wife and his brother it was ascertained definitely that he had never been away from the Birmingham district, but for some weeks he had complained of liver pains, by which he had not appeared to be much inconvenienced. He said his bowels were open freely two or three times a day.

Condition on Admission.

He looked extremely ill, and was perspiring freely. His face showed many dilated veins. Temperature 102.4°, pulse 104, respirations 28. His tongue was covered in the centre with a brownish glaze, but was moist at the edges; his abdomen was distended; his respiration was jerky, and on taking a deep breath he complained of pain below and to the right of the umbilicus. There was no eruption. The liver dullness was not increased; the spleen could not be felt; the heart was not enlarged, sounds normal. The left side of the chest was normal, except for some crepitations at the base; on the right side there was dullness with diminished breath sounds, and absent tactile vocal fremitus at the base; on exploration with a needle no fluid was obtained. Widal reaction negative.

After-History.

Four days after admission he passed a stool containing a considerable quantity of blood. The dullness and diminished breath sounds on the right side extended gradually nearly up to the spine of the scapula, and on November 27th, on exploring with a needle, some blood-stained serum was withdrawn and 15 oz. of fluid were removed. This fluid was blood-stained and contained pus cells. Pulse 120, respirations 32 to 36. There had been no more diarrhoea; in fact, the bowels only acted after enemata. On November 30th he became suddenly worse, and died in the afternoon.

POST-MORTEM EXAMINATION.

Heart.

The heart weighed 11 oz., and was enlarged, ovoid in shape; area of thickened epicardium on anterior surface of left ventricle; right auricle dilated, wall thickened. Right auriculo-ventricular valve admitted three fingers easily and appeared healthy. Right ventricle filled with yellow clot; its wall thickened. Left auriculo-ventricular valve admitted two fingers and showed chronic thickening. Aorta and coronary arteries healthy.

Lungs.

Right 23 oz., left 18 oz. Right pleural cavity contained 1½ pints of slightly blood-stained fluid. Right lung bound down to diaphragm by fairly recent adhesions; the lung was collapsed, and there was a calcareous nodule in the upper lobe. Left lung free from pleurisy; on section congested; two small calcareous nodules in the upper lobe; no tubercle in bronchial glands.

Abdomen.

No excess of fluid in the peritoneal cavity. Recent adhesions in the right iliac fossa which limited an abscess around the head of the caecum. Stomach and small intestine showed nothing of note. Caecum and large intestine distended and walls thickened. The blind end of the

caecum communicated by rupture with the abscess cavity in the right iliac fossa, but the opening was plugged by a slough. On opening the gut a large ulcer with black adherent slough was seen to occupy the caput caecum coli. Passing upwards along the ascending colon there were other smaller ulcers, most of which were about the size of a small pea; their margins were raised and overhanging, and their floors were occupied by firmly adherent sloughs (Fig. 1). There were also numerous small nodules in the submucous coat of the bowel opening by minute apertures on the surface. These appearances were visible throughout the transverse colon, but faded away in the descending part. The contents of the bowel were black and tarry. The appendix was enlarged but not ulcerated. The mesenteric glands were enlarged, pale, and firm.

Liver.

One hundred and two ounces. In removing the organ an abscess 5 in. in diameter was opened; it contained brownish-red pus and masses of necrosed liver substance. The abscess was bounded posteriorly by the diaphragm and the abdominal wall; it was about the size of a fetal head (Fig. 2). The liver in the vicinity was pale and necrotic.

Kidneys.

Right 7½ oz., left 9½ oz. Both organs were soft and flabby; the cortices enlarged and pale, but the capsules were non-adherent.

Spleen.

Nine and a half ounces, enlarged, pale, and soft. Cultures in broth and in agar were made from the ulcers in the large bowel and from the contents of the liver abscess. The former showed streptococci, the latter proved sterile.

MICROSCOPICAL EXAMINATION.

Sections of the large bowel show as their most conspicuous feature a uniform thickening of the submucous coat, which is partly due to the increase of the fibrous tissue, but in part also caused by exudation of fibrin and cells. There is diffuse catarrhal inflammation of the mucous membrane. The smaller ulcers represent flask-shaped excavations in the submucous coat (Fig. 3), their margins are raised and are formed by overhanging mucous membrane which is the seat of advanced catarrhal change; the floor is formed by the outer portion of the submucous coat, and the centre is occupied by a slough composed of necrotic tissue, inflammatory cells and exudate with occasional amoebae.

Other micro-organisms were not as a rule to be found in these ulcers except in the more superficial parts. The tissues around showed a considerable amount of infiltration with leucocytes and fibrin. Amoebae could be seen, but they were not numerous in the neighbourhood of the smaller ulcers. These ulcers seem to develop as a lesion of the mucous membrane, as in all the areas of necrosis examined by us we have invariably found a breach of the mucous membrane, although it might be scarcely larger than a pinhole. Dopter has described three stages in the process of the formation of these ulcers: (1) Stage of catarrhal inflammation; (2) pre-ulcerative stage characterized by necrosis of an area of the mucous membrane and submucous coat; (3) stage of ulceration. This description is in accordance with the facts as observed by us.

The larger ulcers extend, as a rule, to the muscular coat; their margins are formed by necrotic tissue containing the debris of inflammatory cells and fibrous tissue, with numerous bacteria and amoebae. Passing beyond the zone of necrosis amoebae become more numerous, and inflammatory cells of various kinds may be found. Many of the latter are large, round, and vacuolated, and are often difficult to distinguish from amoebae. Such cells are probably chiefly endothelial in origin. Another type of cell which is found in large numbers is oval, with branched processes and a single nucleus, its protoplasm containing large numbers of strongly basophilic granules.

The lymphatics and blood vessels in the neighbourhood of the ulcers were dilated, and the endothelial cells lining them were swollen.

The Amoebae.

The amoebae could be demonstrated by any staining method, but the following gave the best results: Stain section in carbol-thionin blue for eight or ten minutes

wash in water, then rapidly in 1 per cent. acetic acid in water; wash again in water, dehydrate; clear in xylol, mount. By this method the amoebae may be distinguished from other cells by their deeper purple colour, as in Mallory's method. When they are properly stained, the amoebae appear as circular or sometimes irregularly shaped cells with finely granular protoplasm containing numerous vacuoles (Fig. 4). They sometimes contain basophilic granules, but rarely show other inclusions, and, although some were in close contact with streptococci, we have never seen the latter inside them. The nucleus may or may not be visible, but when present it varies much in shape, size, position, and staining reaction. The amoebae were most numerous in the tissues immediately surrounding the ulcers in the submucous and muscular coats, in the tissue spaces, in the lymphatics and blood vessels. The truth that the amoebae were actually invading the tissues is demonstrated by the position in which they were found, and also by the fact that not infrequently they have been fixed in the act of projecting their pseudopodia (Fig. 5). They were also found in the sloughs, but, so far, we have failed to see them in the glandular acini. Numbers of other organisms—streptococci and bacilli—were found in the more superficial parts of the sloughs.

The enlarged mesenteric glands showed catarrh of their sinuses, and overgrowth of fibrous tissue, but no amoebae were found in them.

The liver showed a widely-distributed increase of fibrous tissue around the portal tracts, which are also infiltrated with inflammatory cells.

As the neighbourhood of the abscess was approached areas of necrosis were to be observed, but they were not especially associated with the central veins as described by Councilman; in these areas the place of the degenerated liver cells was taken partly by dilated capillaries, partly by young fibrous tissue, and they resembled very closely the red areas met with in acute yellow atrophy. Many of the vessels (chiefly the veins) were thrombosed, the thrombi being found in all stages of organization. In the neighbourhood of the abscess the columns of liver cells were flattened, and showed all stages of degeneration. Amoebae could be seen in close contact with fairly healthy liver cells (Fig. 6), and also inside the blood vessels and bile ducts (Fig. 7). The contents of the abscess consisted of strands of fibrous tissue, necrosed liver cells, leucocytes, both lymphocytes and polymorphs, and amoebae. Councilman did not find polymorphs in the liver lesions in his cases, and he considers that a pure amoebic lesion does not attract such leucocytes. Certainly at the spreading margin of the abscess these cells were not present in excess, and there was no evidence that amoebae were attacked by them, but deeper in the abscess, where degeneration and liquefaction of cells were in process, they were numerous.

The amoebae in the liver lesions showed characters similar to those in the ulcers, but cell inclusions were more frequently present. There were at least three types.

The first type consisted of fine granules fairly uniform in size, and not suggestive of pieces of ingested chromatin; it is not impossible that these may be the chromidia described by Schaudinn and by Lesage as the first step in the formation of a capsule for the resting stage of the organism. Schaudinn only observed the development of these resting forms in the living subject during the healing of the lesions, but doubtless they are also formed under disadvantageous conditions in the tissues at any time, although Wenyon has not observed them.

The second type of inclusion was a comparatively large round or sausage-shaped body, with well-defined margins (Fig. 8), which took on basic stains very deeply; these may possibly be chromatin or other products of cell

degeneration, but they have not the appearance of the usual chromatin inclusions of phagocytes.

Thirdly, we observed the thin rod-shaped bodies which have been described by Councilman as curiously like tubercle bacilli; we make no suggestion as to their nature.

In support of the view that resting forms occur, we may say that we frequently met with rather small amoebae with well-defined, darkly stained margins, which gave the impression of being enclosed in a somewhat opaque envelope (Fig. 9).

REMARKS.

The chief points of interest from a pathological point of view in the case are:

1. Ulcerative colitis, in which the smaller ulcers are circular and flask-shaped—*bouton de chemise* of French authors—with overhanging edges and relatively small circular openings into the lumen of the bowel and adherent sloughs; one of the larger ulcers had perforated into the peritoneal cavity.

2. The presence of an enormous abscess in the posterior part of the liver, the pus of which gave no growth on inoculating in ordinary media.

3. Lastly and most important, the presence of amoebae in the ulcers and the liver abscess and in the tissues around these lesions.

We believe we are warranted in concluding that the pathogenic organism in this case is the *Entamoeba histolytica* (Schaudinn), and that the case is one of amoebic dysentery with consecutive liver abscess, of the type which we are accustomed to call "tropical"

dysentery. The appearance of the ulcers alone is sufficient evidence of the nature of the condition. If this be admitted, and as the patient had never been out of England, or, indeed, away from the Birmingham district, the case presents a peculiar interest, inasmuch as, so far as we have been able to ascertain, it is the first observation of the kind which has been recorded in Great Britain. Jurgens has mentioned a case which occurred in Berlin, and

Caussade and Joltrain have recorded one from Paris, while Kartulis (1906) has stated that Scandinavia, Great Britain, Spain, and Portugal are the only European countries from which cases of amoebic dysentery have not been reported. Davidson (1908) remarks that the disease has not been recognized, but is, perhaps, not entirely absent from England.

The next point of interest is how did the individual become infected? The medium of infection in dysentery is, as with typhoid fever, usually water, less frequently food contaminated by dust or flies. Given a case of tropical dysentery—that is, dysentery acquired in the tropics—in the neighbourhood of the patient (and such cases are from time to time imported into England) we have a source of possible infection from which contamination of food or drink during warm weather is all that would be required for the communication of the disease.

The perforation of the caecum coli is worth noting, as Kartulis describes its occurrence, but indicates that it is infrequent. The distribution of the ulceration was probably that most frequently seen—that is to say, it was most marked in the caecum, extending thence as far as the descending colon, but becoming progressively less marked. The size of the liver abscess indicates that it had been in existence some time, and, in fact, everything points to the disease having run a chronic course without marked constitutional symptoms.

Owing to the latter circumstances, the clinical history is deficient. The nature of the case was not recognized during life; it was regarded as a septic fever of unknown origin with haemorrhagic purulent pleurisy. The patient made no complaint referring to the liver after his admission to the hospital, but the failure to recognize enlargement of the organ was probably due to the

distension of the bowel. Although he gave a history of his bowels having been freely open before admission, he did not speak as if he had been troubled by diarrhoea, and after his admission the bowels only acted with enemas. Haemorrhage from the bowel occurred only once, but was profuse. Strong regards this symptom as a rare occurrence in dysentery, and in the cases in which he met with it he has, he says, generally found it associated with abscess of the liver. He speaks of it as being of peculiarly fatal prognostic significance, and in this case death followed in a very few days. He believes that the reason bleeding does not take place more often is because the arteries are commonly thrombosed or are the seats of more or less marked endarteritis. The immediate cause of death was no doubt heart softening, as there was no general peritonitis.

Although the connexion between abscess of the liver and dysenteric ulceration has been well known for many years, attention has been drawn in recent times to the want of harmony between the statistics of the two diseases. This is probably explained by the special connexion between the amoebic form of dysentery and hepatic suppuration. Bacillary dysentery is the more common, and more often occurs in epidemics, and is more likely to attack people whose habits and circumstances are insanitary, as is the case with natives in India, among whom dysentery is much more common than among Europeans. Yet, on the other hand, Europeans are more liable to abscess of the liver, as, according to Buchanan, the ratio was in natives 1 abscess to 628 cases of dysentery, and in Europeans 1 to 18. We have no figures that enable us to say what is the actual proportion of abscesses occurring in amoebic dysentery, because there are no statistics which distinguish between the two forms; if we had them we might be able to determine this point, but many observers have pointed out the relative rarity of abscess in bacillary dysentery. Any cause which gives rise to congestion of the liver would favour the occurrence of abscess, and therefore we may expect to see it in those persons who live sedentary lives, indulge freely in alcohol and in the other pleasures of the table; this in effect is the case. It is more common amongst Europeans than amongst natives, comparatively rare amongst European women and children, more often met with in rich natives than in poor, seldom met with in total abstainers, and according to Sandwith is only seen in those natives of Egypt who are addicted to alcohol. The patient in the present case had all the appearance of a man who had abused alcohol.

The occurrence of a case of amoebic dysentery in England must be accepted as a rarity and an event which must be only exceptional. As amoebae readily die at temperatures below 75° F. the conditions must be unusual which permit of their survival outside the body. Hence, in all probability, the disease, although no doubt imported into this country from time to time, rarely spreads; that it may do so, however, when circumstances favour it, seems to be established by the present case.

BILHARZIOSIS OF WOMEN AND GIRLS IN EGYPT IN THE LIGHT OF THE "SKIN-INFECTION THEORY."

By DR. A. LOOSS,

PROFESSOR OF PARASITOLOGY, SCHOOL OF MEDICINE, CAIRO.

IN THE BRITISH MEDICAL JOURNAL of October 31st, 1908, page 1355, Mrs. B. S. Elgood, Assistant Medical Officer, Education Department, Egypt, published a very interesting article on Bilharziosis among Women and Girls in Egypt. Whereas before nothing definite had been known, and many had even thought that bilharziosis was rare among the women in Cairo and other towns of Egypt, Mrs. Elgood proves the contrary. An examination of the urine of the girls of two middle-class schools in Cairo revealed the fact that, out of 40 girls aged 12 to 16 of one school, 11—that is, a percentage of 27.5—were infected. In the second school, attended by 79 girls aged 6 to 13, 39 girls were boarders; among them, 8—that is, a percentage of 20.5—showed bilharzia eggs and blood in their urine; the other 40 girls were day pupils; among them, 11—that is, a percentage of 27.5—were infected. After these results obtained from girls, the author was very much surprised to find an almost total absence of infection in adult women; among 62 female patients of the Kasr-el-Ainy Hospital, consisting of the respectable lower middle classes from all parts of Egypt, only 2, or a percentage of 3.2, were found to void bilharzia ova. In her own eight years' practice among women in Egypt, the author says that she has never been consulted by an adult for bilharziosis, and that in spite of frequent examinations of urine for other purposes, she only once accidentally found bilharzia eggs.

Thus far the results of Mrs. Elgood's investigations form indeed a very valuable addition to our knowledge of the distribution of bilharziosis among the inhabitants of Egypt. Until within the last few years the disease had appeared to be practically confined to the male population of the rural districts, for the most numerous and the most severe cases observed had all been peasants, among whom no age, except the years of early boyhood, seemed exempt. Infection of women was, to judge from the hospital records, comparatively rare, even in the country. With regard to the peasant women, the researches of Moh. Bey Talaat, undertaken *in loco*, elicited the interesting difference that the percentage of those affected was greatest among the poorest, whose women-folk work in the fields together with, and in the same fashion as, the men, and that it was lowest, or practically nil, among the best situated, whose women do not take any part in the field work of their male relatives. The native population of the towns had during all this time appeared to be generally free from infection, for no cases from towns had come under observation in the hospitals. Here, the researches of Engel, Kantsky, and others brought about a change; it was shown by these authors that in Cairo the adult men are indeed for the most part free, or show only traces of old infections, but that boys may have bilharzia eggs in their urine in as high a proportion as 80 per cent. of the cases examined. In many of these boys no external symptoms of the affection were noticed. This general picture of the distribution of bilharziosis among the native population of Egypt is completed, in a most instructive manner, by Mrs. Elgood's observations, which show that what had been known about men is to a very large extent valid also for the women of Cairo in particular, but undoubtedly of other towns of Egypt as well.

In addition to her actual observations, Mrs. Elgood makes some inquiries into the previous history of her cases, and thus collects a number of facts which she thinks throw light on the mode of infection. Since it

cannot now be doubted that water is the element by which infection is carried, she turns her attention to the water supply in the houses of the girls and the schools they attended. Inquiries revealed that the girls of the first school had, with one exception, lived all their lives in Cairo; that none had ever bathed in the Nile or a canal; nor had any (with two exceptions) ever run about bare-legged in fields or country roads. As far as they remembered, they had all worn shoes and stockings when out in the streets of Cairo. The water in their houses was supplied by the Cairo Water Company. It was usually stored before drinking in earthenware "Zirs" or "Gullahs" to cool it. At the schools the conditions were the same, only the water was first filtered through a Berkefeld filter into a non-porous glazed earthenware receptacle, from which it was drawn off as required for use into small earthen jars. Nothing could be elicited as to any special ablutions which could have led to the infection of the girls. The general water supply in European households in Cairo is about the same as that of natives. It differs in one respect, as Europeans, however poor, do not usually store their water in Zirs, but either filter it in a Berkefeld or charcoal filter, or use it straight from the tap. The primary water supply common to natives and Europeans has been frequently examined and found to be pure; Mrs. Elgood personally examined the water in the large receptacle and in the small jars used in one of the schools, but no bilharzia miracidia were discovered. There remains the possibility that the native habit of storing the water may favour contamination. The Zirs often stand in open courtyards; they are rarely, if ever, cleaned out in native houses, though in schools they require scrubbing every week. It seems possible, therefore, that these Zirs may be a source of infection.

The results of both observations and inquiries are embodied by Mrs. Elgood in the following conclusions: (1) Bilharziosis is common in young girls, even in those who do not bathe, and who use filtered water only; town children are frequently affected. (2) Bilharziosis is rare in adult women, who may, however, have suffered from it in youth. (3) European women and girls are not known to be sufferers from bilharziosis, though in the towns they drink and wash in water from the same source as natives use. Water, however, is not stored in European households. (4) The infection by bilharzia is probably not mainly due to bathing as has been suggested. It is possibly due to faulty storage of drinking water, or to the eating of raw vegetables and fruit washed in dirty canals or rivers.

In the discussion following the reading of this paper before the Section of Tropical Diseases, British Medical Association Meeting, 1908, Dr. Sandwith, among others, congratulates the Section upon Mrs. Elgood's valuable paper, and adds that it "threw considerable doubt upon Professor Looss's interesting theory of infection by the skin. . . ." It is this latter view—shared, perhaps, by readers of the printed article—which induces me to make the following remarks, for I may say at once that I do not see how Mrs. Elgood's observations, interesting and valuable though they are, can be construed into something like evidence against the theory of infection by the skin if only they are analysed logically and considered, not by themselves alone, but in connexion with the other facts thus far established with regard to the disease and the biology of its parasite.

I begin my discussion with a point which, though of fundamental importance, is yet very often overlooked by authors who formulate theories about the manner in which man becomes infected with parasitic worms. In the case of bilharziosis there is no doubt that the infection is carried to man by water; but the infective agent proper is not water, but the bilharzia miracidium. Any theory of infection is therefore open to objection from the very outset, if it does not equally account for both the passage of the living miracidium from water to the human system and the previous passage of the miracidium from the human system to the same water. On scrutinizing Mrs. Elgood's conclusions one cannot fail to notice that they appear deficient in lucidity, disconnected, contradictory. The reason is that the author totally disregards the first half of the parasite's life-circle. The miracidium is contained in the bilharzia egg, and the bilharzia eggs are voided from infected persons with the urine (or

the faeces). Any water, in order to become possibly infective, must, as an essential condition, previously come into contact, either direct or indirect, with fresh urine (or fresh faeces); under circumstances where such contact is precluded the water is, *ipso facto*, safe. We know, further, that the miracidia are extremely delicate and stand neither decomposition in their surroundings nor drying; old excreta, therefore, which have once become putrid or dry cannot deliver living miracidia to water; receptacles, even if they contained contaminated water, become safe again with completedesiccation. Experiments made with living miracidia have shown, finally, that these are not able to live, even in pure water, longer than thirty to forty hours after their evacuation from the human body. Contaminated water, therefore, loses its infective power again after having been protected from fresh contamination for one or two days.

If we duly consider these facts established by numerous experiments, it becomes obvious that water taken from the tap, either directly or after having been passed through a filter, must be safe; for there is no comprehensible chance for living miracidia to get into it. This non-infective character of the tap water is in full accordance with the absence of the affection in the European and the adult native populations of the town; it forcibly imposes the conclusion that the infection of the children must be brought about in some other way. I may here add in passing that when I first came to Egypt I myself took my drinking water direct from the tap for nearly a year, and occasionally even afterwards, but have never contracted an infection.

According to Mrs. Elgood, the storing of the water in the Zirs, etc., customary among the natives, may have something to do with the infection. To me this would seem utterly improbable from the outset, for the one reason that the adult natives, though they use the same water as their children, remain free from infection or reinfection, whilst the children are largely affected. Mrs. Elgood has examined the water contained in the receptacles and jars in one of the girls' schools, but failed to find bilharzia miracidia. After what has been said above this result was to be anticipated. If I had been asked, I would even have said that such examination was superfluous, unless it was previously shown that there was some positive possibility of the water or the receptacles coming into frequent contact with fresh human urine (or faeces). It is true that especially the lower-class natives are not conspicuous for over-cleanliness; but, so far as my personal knowledge goes, they always keep their Zirs and the various receptacles for drinking in such a way that their contact with urine or faeces is prevented. Thus, I am unable to see how the particular fashion of storing the water used in the Egyptian households should favour the spread of bilharziosis at all, and should in especial favour it among the children to the exclusion of the adults.

Mrs. Elgood finally suggests that the eating of raw vegetables and fruit washed in dirty canals or rivers might probably be responsible for the infection. This idea is not new, and in my view is even less tenable after Mrs. Elgood's observations than it was before. I may first submit that fruit or vegetables, while being brought to town after having been washed in dirty canals or rivers, become either dry, or are in town washed again in the water accessible there—that is, in tap water—at any rate, in water which is most unlikely to contain living miracidia. However, this objection is insignificant as compared with the other evidence, in part brought forward by Mrs. Elgood herself. The lower-class Greeks throughout Egypt, as is well known, have almost completely adopted, as regards food and drink, the habits of the Egyptians; like these, they are fond of certain vegetables, which they consume without further preparation. In many Greek restaurants of the town it is customary to serve, without special order, certain herbs still wet with water before every meal. In the case of the town population the consumption of these vegetables does not, of course, prove anything against the possibility of the infection being carried by the vegetables; for the absence of the affection among the Greeks in town may be due to the fact just pointed out, that vegetables washed in town water are most unlikely to contain live miracidia at all. However, we know that the affection is absent

also in the numerous Europeans (especially Greeks) living in the villages, where the male native population is severely affected. If the vegetables and fruit represented a conveyance by which the miracidia do reach their host, we certainly ought to find the disease about equally distributed among natives and Europeans. What had been known with regard to the male sex has to a great extent been confirmed with regard to the female sex by Mrs. Elgood. Women are rarely affected, in the town as well as in the country, and yet they partake of fruit and vegetables to about the same extent as the men and children. Fruit and vegetables, therefore, cannot be the source of infection.

We thus see that the author's suggestions as to the probable mode of infection would logically lead to consequences entirely different from what we actually know of the distribution of bilharziosis among the population of Egypt. Infection, both by drinking water and vegetables or fruit, are varieties of the "oral infection." I have, in previous articles, pointed out certain biological facts which throw "considerable doubt" upon the existence of this infection; new epidemiological facts elicited by Mrs. Elgood are, for me, apt only to decidedly add to these doubts. As a matter of fact, I contend that infection by the mouth does not exist.

Let us now see how facts, new and old, fit in with the skin infection theory. If we exclude infection by the mouth, infection by the skin remains the only possible; I, for one, cannot imagine a third possibility of infection. The idea that the miracidium might, during bathing, or during the ablutions customary among the Mohammedans, enter the urethra or the anus is utterly improbable for general helminthological reasons, and, in addition, contradictory to a number of biological and anatomico-pathological facts. For the sake of brevity, I will not enter into details. Speaking of the theory of infection by the skin in general, I may first recall the fact that it was almost simultaneously advanced by G. S. Brock and myself, but that we both arrived at our conclusions independently and from very different starting-points. Brock, investigating the previous history of his patients, found that a feature common to all was their predilection for bathing, and thus accused bathing in particular as the cause of infection; I, investigating the life-history of the parasite, found that the mode of infection by the mouth—a *priori* alone probable—met with some insurmountable biological obstacles, and was thus driven to the conclusion that infection must take place by way of the skin. I do not deem it necessary to mention details here; they may be found in my article quoted, but apparently not read, by Mrs. Elgood; at any rate, she does not allude to what I said in that article of the possibility that the affection of the children in particular might be accounted for by skin infection. She only points out that

If bathing were the sole, or even the principal, cause of infection, the women of the working classes in the villages and country towns should be the severest sufferers, for they stand for many minutes, once or twice daily, knee-deep in the canals and in the river washing their clothes and filling their waterpots, and yet they do not appear to suffer.

This objection, based upon an undeniable and well-known fact, may seem convincing to many, and yet it does not meet the case. It again entirely overlooks the important factor mentioned above, that water, though undoubtedly the conveyance of the infection, is not identical with the miracidium, the agent of infection. In order to render infective the water with which the clothes are washed and the waterpots filled, the women ought to urinate or to defecate into it. As far as I have seen myself and learned by inquiries they never do so, but even if one or two actually did so the act would not at once effect a contamination of the water. For we know from the statistics that bilharziosis is rare among the women throughout the country; assuming that 3 per cent. are infected, thirty-three women might soil the water without consequence, and only the thirty-fourth would produce miracidia which might attack her companions. The two circumstances here mentioned, if taken together, show, I think, clearly that the absence of bilharziosis in peasant women is due to factors quite independent of the mode of infection.

There remains the possibility that the water with which the women wash their clothes and fill their waterpots

may still contain some miracidia derived from an infected man who either had previously contaminated the water at the same spot, or who, at about the same time, had contaminated it at some little distance from the women. Such miracidia may certainly infect, but the probability of their doing so is very small; for it must be remembered (and everybody who is familiar with the habits of the miracidia will know) that when once free from their egg shells they speedily disperse in the water to all sides, and the chance of reaching a suitable shelter considerably decreases for the individual miracidium with time and distance. The more I think of this latter circumstance the more I become convinced that the chief foci of infection—that is, the place where strong and repeated infections are contracted—cannot be found in large bodies of water, as rivers, canals, ponds, etc., but must be sought in small accumulations of water, in which the miracidia, once introduced, cannot become widely dispersed. The fact that the large majority of peasant women remain free from infection, in spite of their old habit quoted by Mrs. Elgood, decidedly supports this view. Thus, the rarity of the affection among peasant women may be considered as evidence against bathing or standing in certain large waters being the cause of infection, but it is certainly no proof against the infection by the skin in general.

We will now see if the skin infection, supposing that it takes place as I conceive it, would be able to account for the peculiar distribution of bilharziosis among the population of Egypt. One of the most remarkable features of the disease is, in town, its almost entire limitation to native children; in the agricultural districts a very similar limitation to the male natives of all ages is to be noted. These facts enable us to formulate positively the conclusion that, quite generally speaking, the infection with the parasite must, in town, take place under conditions which are easily and often realized during childhood, but cease to be realized with the growing age; for reinfections do not take place in town, the adults are either free, or show traces of old infections only. These conditions must, further, be the same as prevail throughout life for the male native population of the country; for these reinfections are very common, and it is a frequent occurrence to find in *post-mortem* examinations of old people comparatively recent infections besides more or less conspicuous traces of old ones.

To render an infection by the skin at all possible we have seen that the following conditions must be realized: An infected person must urinate (or defecate) in a place where there is water, however small the quantity. The place must remain moist for some time, but not longer than thirty to forty hours. Within this period another person must bring some part of his skin for some time into actual contact with the moisture. If these conditions are fulfilled, the miracidia have the *possibility* of getting from man to water, and from water back to man; their life-cycle may be closed.

The probability of their bringing about a fresh infection is governed by the following facts: When in contact with water the miracidia leave their egg-shells without delay. It practically takes them a few minutes only if the weather is warm. They are, like the miracidia of other trematodes, ready at once to enter a new host, if there is one. The moist places thus become infective almost immediately after contamination. They also have at that time their greatest infective power, for the living miracidia are most numerous in them. As time goes on numbers of miracidia die, and thirty to forty hours after evacuation none are left alive. The infective power of the moist places thus gradually decreases, and is again nil at the end of one or two days, even if they remain moist. A recontamination must take place in order to render them infective again for a short period.

I have tried to show in previous articles that these conditions for infection are realized, almost throughout life, for the male peasants during their field work. They are not realized for the great majority of the peasant women and for the European population of the rural districts. The incidence of the disease thus coincides with what is theoretically to be expected from the point of view of the skin-infection theory. I may hint, in passing, at the interest the results of Moh. Bey Talaat gain in the light of that theory.

Turning to the affection of the children in town, we

will try to see if similar conditions exist to explain their infection to the almost complete exclusion of the adults. The moist places demanded for infection are to be found plentiful about town; in the streets there remain puddles for several days after each rain, or for several hours after each watering; the courtyards of the houses also are often watered, especially in the warm season; in the neighbourhood of the Zirs (whether they be placed in the houses or in the yards) the overflowing water impregnates the ground and keeps it almost constantly wet, etc. In many Arabic houses waterclosets are an unknown institution, or they are of the most primitive type. The calls of Nature are often obeyed in the streets, oftener in the courtyards, especially for urinating. There is thus sufficient occasion for the ground to become over and over again populated with live miracidia; their short life is of no consequence. There only remains the host to supply the miracidia, and another host to take them up again.

Owing to the peculiar restriction to children exhibited by the disease as seen in town, the suppliers of the infective material must be, first and foremost, children; in nine cases out of ten an infected child must have become infected from another child; adults can only play a minute part, if any, in the propagation of the germs, for they evacuate none. We are thus led to the conclusion that gatherings of children in moist surroundings (I am thinking here especially of the courtyards of their houses) must represent the chief occasion for their infection. I may repeat in this connexion that, in my opinion, the association of the peasants in groups, while at work in the fields, provides the most evidently favourable condition for their frequent reinfections. Nothing is thus far known about the age at which the infection of the children takes place. Judging from a purely helminthological point of view, the tenderest age would be the most favourable, for we know from numerous experiments made with different kinds of parasites that their germs develop easier and in larger numbers in young hosts than in old ones. It is not yet known either how long it takes the miracidia to make their way into the skin. They may require a few minutes only or they may require an hour; however, it is certain that their chances are the better the longer the skin remains exposed to their attacks.

In the poorer Arabic families the children are very little looked after; they are for the most part left to themselves. More or less scantily dressed, they sit, or creep about, or play on the ground, either in the house or in the yard. As might be expected, they are not in the least particular as to how or where the calls of Nature are obeyed. It is thus evident that during this early period of childhood bilharzia miracidia, if present in the ground, would have abundant opportunity of entering their bodies. When the children learn to walk this opportunity becomes lessened; it becomes more so the older they grow. If once infected they do not, however, cease to produce infective material for their younger brothers and sisters, or other children who may be with them. In this way the miracidia necessary for infection would be supplied. We would practically have the propagation of the disease from child to child, as is deduced above. It is difficult for the adults to become infected after this same fashion. They have their occupation about town. They do not sit or lie for hours on the ground more or less naked; they do not play with their hands in the mud, etc. The male peasants, on the other hand, while at work in their fields during the whole of the wet season, do stand for many hours daily with their feet in the moist ground, they do work with their hands in the mud, etc., and they do become infected and reinfected with bilharziosis throughout their lives. Thus, the other conclusion formulated above—namely, that the infection with the parasite must in towns take place under conditions which are easily and often realized during childhood, but cease to be realized with the growing age—would be verified. We also see the analogy between the habits of the children in town and those of the adult males in the country; the restriction of the affection chiefly to these two categories of the total native population becomes comprehensible.

As regards the European population, I am not familiar with the conditions in their houses; several things, however, are easy to observe. Thus, even among the poorest, one hardly if ever sees such neglected children as are often

met with among the poor native population. In the streets it is a rare occurrence to see European children, even of the lower classes, mix with the poor native children. I have never, in spite of special attention paid to the circumstances, happened to see a European child paddle in the street puddles as the native children are fond of doing. The lower-class Greeks, in particular, do not seem to be at all fond of water. The more the European children are looked after, the cleaner they are kept, the less they mix with native children, the more difficult it naturally becomes for any miracidia contained in the ground to get access to them. Since, furthermore, their relatives and playmates are generally free from infection, there are in the neighbourhood of the European children no miracidia either which might infect them. Under such circumstances, it becomes comprehensible that bilharziosis does not spread to any noticeable extent among the lower-class Europeans, although their food and drink is essentially the same, and derived from the same source, as that of the lower-class natives.

In Mrs. Elgood's article some stress is placed on the evidence given by the girls that they usually wore shoes and stockings when out in the streets; that they never bathed in the Nile or a canal; that they were never allowed to paddle; that their mothers never washed clothes or vegetables in the Nile, etc. Admitting even that all these statements are reliable, and that the girls of 15 and 16 still perfectly remembered what they had done when they were 5 or 6, the circumstances enumerated have, according to my view, nothing to do with the actual event of the infection of the children. After what has been said above, the early years of 1, 2, or 3 must be considered as those most favourable for acquiring the disease; for during this period of life the conditions necessary for infection are most often and most easily realized. So far as I can see from the literature, nothing positive is as yet known as to the occurrence of bilharziosis at that early age. The investigations of Mrs. Elgood do not throw light on this point. As a matter of fact the girls, at the time of their examination, were quite unaware of their suffering, nor would they admit that they ever passed blood either with urine or after it; none of them complained of pain or bleeding on micturition. There is thus nothing to prevent us from assuming that the girls had already been infected more or less long before they became able to think of themselves. The same may be said with regard to the boys that had been found infected by Engel, Kautsky, and others. The actual proof that children of tender age may already be suffering from bilharziosis is thus as yet lacking; I have, however, little doubt that it will be forthcoming as soon as observations in this direction are made.

The fact that children of 15 or 16 still pass numerous bilharzia eggs is no proof against the assumption that they were, once only, infected at the age of 1 or 2. We already know a number of cases in which adults still passed plentiful eggs fifteen and more years after they had left the places where infection alone seemed possible. It is not necessary, on the other hand, that every infection should last for so long a time. The duration of the suffering certainly depends to a large extent on the intensity of the infection; a feeble person may die off within five or six years, whereas a strong one lasts much longer. In addition, the point remains, that if an affection noticed, say, for five years really lasted only these five years, the evidence collected by Engel, Kautsky, Mrs. Elgood, etc., shows that children of both sexes may be infected for long years without becoming at all aware of the fact.

SUMMARY OF CONCLUSIONS.

1. Any theory about the mode of infection with bilharziosis, in order to be at all acceptable, must (a) account for the passages of the miracidium both from man to water and from water back to man; it must (b) duly consider both the habits of the host and the biological peculiarities of the parasite.

2. The theory of the infection taking place by the mouth (along with food and drink) must be refuted, because it is irreconcilable (a) with certain biological peculiarities of the miracidium, (b) with the general distribution of the disease among the population of Egypt.

- (3) The theory of infection by the miracidium entering the urethra or the anus is (a) utterly improbable for

general parasitological reasons; (b) in contradiction with a number of biological and anatomic-pathological facts (for example, the incapability on the part of the miracidium to resist the action of acids, even if very diluted; the part played in the infection by the liver, etc.).

4. The theory of infection by the skin is in accordance with all the facts thus far known (a) of the biology of the parasite, (b) of the distribution of the disease among the population (native and foreign, town and rural) of Egypt. It shows (c) how the chief sufferers—the children in town, the adult males in the country—live under conditions which, from the epidemiological point of view, are essentially the same, and give the miracidia (d) the opportunity of passing, within the short time of their life, from man to water and from water back to man.

IV.—UTERINE CONTRACTIONS.*

SINCE uterine muscle consists of involuntary muscle fibres, one may take it as an accepted fact that most of those chemical substances which cause contraction of other involuntary muscle fibre throughout the animal body, whether produced by metabolic process normally or in specific circumstances or by experimental and therapeutic means, will also cause uterine contractions.

The object of our investigation was to discover what substance or substances, which might be said to exist in the blood normally, influenced the contraction of the uterus in respect to the ordinary contractions which are supposed to occur in the unpregnant uterus, and also those of the pregnant organ. In all our experiments we used rabbits, and our technique was as follows:

The rabbit was anaesthetized with ether, and, when fully under the influence of this anaesthetic, laid upon a heated table. The trachea having been exposed, tracheotomy was

Fig. 1.—Uterine cannula.

performed, and a tube connected with an electric bellows tied in position. The skull-cap was then trephined and the rabbit pithed, the brain being entirely destroyed, and the cranial cavity packed with wool plugs saturated with hot saline solution.

The abdomen was next opened with a 1-in. incision and the uterus and vagina identified. A small incision was made in

a.* The experiments recorded in this paper were carried out in the Physiological Laboratory in the University of Liverpool, and we are much indebted to Professor Sherrington for the facilities afforded.

the posterior wall of the vagina, close to the insertion of the cervix, and a special glass cannula, with a rubber-covered neck (see Fig. 1), connected with a one-arm water manometer, was carefully passed through the vulva, up the vagina, through one of the cervixes, and into a uterine cornu. This was easily accomplished by directing the progress of the cannula through the small incision in the vagina. Before being passed into the uterus saline solution was allowed to flow through the cannula in order to prevent the entrance of air.

As soon as the head of the cannula was well in the uterus a soft worsted ligature was tied firmly round the cervix above the vagina, binding it against the rubber-covered neck. On one or two occasions elastic was used as the ligature material. The uterus was then returned to the abdominal cavity, placed in a normal position, and the abdomen closed. Enough saline was allowed to flow into the uterus to distend it slightly, but only so far as to support a column of saline solution 1 in. or 2 in. in height in the single-arm manometer. This manometer was next connected with a special bellows apparatus, very kindly made for us by Professor T. G. Brodie (see Fig. 2). This apparatus consists of a membrane finger-cot attached to a glass tube which is passed through a cork, the front of which is cut at an angle. To the lower end of this a card lid is attached to support the finger-cot. A card lid with a membrane hinge rests upon the protruding rounded end of the finger-cot. To the centre of this lid is fixed a piece of cork, to which a straw lever is attached by means of a needle. A glass writing point swinging from the distal end of the straw records the uterine contractions upon smoked paper revolving on a Brodie's kymograph apparatus, for it will be clear that as the uterus contracts the saline solution is driven up the manometer tube and the finger-cot distended. In all tracings the writing points were travelling from right to left, as indicated by the arrows below the blood pressure tracings.

The carotid artery was next connected with the mercury manometer, and the blood pressure recorded. The time was marked in seconds by means of an electric connexion with a clock.

The reagents used were in all cases injected intravenously, and the smallest doses compatible with a definite result employed. Control injections of simple saline solutions were frequently used.

It may be urged that pithing produces a condition of intense shock and low blood pressure. This, of course, is true; at the same time it is probable that the blood pressure is acted upon in much the same way, if in less degree, under these conditions by the reagents we employed, as would have been the case had pithing not been performed. Certainly pithing seems to have little effect on uterine contractions. On the other hand, we found it absolutely impossible to get satisfactory results under ordinary anaesthesia, owing to the variations in blood pressure, and the irregularity of uterine contractions—probably due to the impossibility of keeping the animal all the while in the same state of anaesthesia.

In regard to our method of recording uterine contractions, we consider it the most perfect yet utilized, in that alterations of the total uterine content only are recorded; and, further, that the uterus is acting under practically normal conditions—the slight stimulus of saline solution under a low pressure being negligible from a practical point of view. The methods used by Cushny,¹ Dale,² and others are open to the objection that the uterus is exposed—even though it be in a bath—and, further, that isolated muscular contractions only are recorded, instead of altera-

Fig. 2.—Recording bellows.

tions in the total content. Now we have found that contractions of the uterus may occur without the uterine content being altered at all. That is to say, the uterus may relax at one part while contracting at another. In our opinion the total alteration in the content, or, in other words, the expulsive force of the uterus, is the most important result of uterine contraction, and it was this we wished to measure; hence our employment of the method already described.

Before passing on to a consideration of the results obtained, we would like to point out, in addition to the fact just mentioned of peristaltic contraction, in which a relaxation compensates a contraction, that we have found the contractile power of different uteri to vary enormously according to the size of the rabbit and its age. In regard to the former point, it will be noticed that a great variation occurs in the size of the contractions in

Fig. 3.—Inactive uterus showing no contraction. (Reduced about one-half.)

the different tracings. This is almost entirely dependent, subject to the conditions to be mentioned directly, on the size of the uterus, or, in other words, on the age and size of the rabbit. In addition to these factors, we must also point out, however, that the non-menstruating and non-pregnant uterus does not normally contract at all (see Fig. 3 and subsequent figures of inactive uteri). We have reason to believe that this applies to the uteri of wild

Fig. 4.—Menstruating uterus showing normal expulsive contractions. Note—Drum revolving faster than in Fig. 5 and in most of the other tracings. (Reduced about one-half.)

rabbits in winter months (see Paper III). We shall for the sake of brevity refer to these as "inactive" uteri.

The menstruating uterus appears to be in a state of more or less regular expulsive contraction (see Fig. 4), and likewise the pregnant uterus (see Fig. 5), once the uterus when in this condition is interfered with. Unfortunately it is impossible to measure contractions without some interference, but we obtained conclusive evidence in one instance, in which the sacs were unruptured, that leads us to believe that the pregnant uterus does not normally contract expulsively. That is to say, any contractions which normally occur are compensated by relaxation at the same time. Our tracings of the contractions of the pregnant uterus are, therefore, from those experiments in which the membranes had been ruptured.

Fig. 5.—Pregnant uterus showing normal expulsive contractions. (Reduced about one-half.)

In our experiments we have used all three varieties of uterus: The pregnant, the menstruating, and the virgin non-menstruating.

We have tried the effect of the following reagents upon these uteri by intravenous injection:

1. Ovarian extract.
2. Thyroid extract.
3. Pituitary extract.
4. Adrenal extract.
5. Placental extract.
6. Uterine secretion.
7. Calcium salts.

In general, we may say that in some cases the virgin non-menstruating uterus was affected, but that in those

cases where any contraction was obtained it was more marked in the case of the menstruating uterus, and most marked in the pregnant uterus. That is to say, a uterus that can be caused to contract by any reagent reacts more readily and violently during menstruation and pregnancy.

Fig. 6.—Menstruating uterus showing normal expulsive contractions. (Reduced about one-half.)

We have, in short, been unable to obtain those paradoxical effects, noted by some observers using different methods, of relaxation in the non-pregnant and contraction in the pregnant uterus. Such results seem foreign to what one would expect, and are not, as we say, borne out by our

Fig. 7.—Menstruating uterus: effect of ovarian extract. (Reduced about one-half.)

results. In most of the experiments we were also able to note the effect of our reagents upon the blood pressure.

1. Ovarian Extract.

The ovarian extract used was kindly prepared for us by Mr. H. H. Dale, of the Wellcome Laboratories. It was made by extracting fresh sheep's ovaries with cold saline solution containing a little chloroform. The extract was filtered first through paper, and then under pressure through a Berkefeld candle. A crystal of thymol was added to act as an antiseptic; 1 c.cm. of this extract contained 0.25 gram of fresh ovary.

(a) This extract has no effect upon the inactive uterus.

(b) Upon the menstruating uterus the effect is well marked, as illustrated by the gradually increasing effect of

Fig. 8.—Menstruating uterus: effect of ovarian extract in repeated doses. (Reduced about one-half.)

a series of intravenous injections of 1 c.cm. of the extract. This is shown in Fig. 6. The action is not excessively energetic, but still it is quite evident. Fig. 7 illustrates the effect in another rabbit, whose uterus was also menstruating. In this case a more or less tetanic spasm was produced.

(c) The pregnant uterus is affected in a somewhat remarkable manner by ovarian extract. The strength of the contractions are in no way lessened, but the immediate effect of an injection appears to be the stopping of the

* Verbal communication, Dr. F. E. Taylor.

impending contraction. This is shown in Fig. 8, in which only one injection is illustrated. A subsequent injection produced the same effect, but with a slightly shorter interval, and a third injection hardly showed the effect at all, antibodies being probably formed in the blood by that time. We may say, however, that in the case of other

uterine contractions. In Fig. 9 this result is seen after one injection. The results of a subsequent injection into the same animal are illustrated in Fig. 9 *continued*, where a general convulsion was noted after the third injection.

(c) On the pregnant uterus the effect is the same as that upon the menstruating uterus, only more marked.

Fig. 8.—Pregnant uterus: effect of ovarian extract. (Reduced about one-half.)

pregnant uteri an increase in the strength of the contractions only was observed.

The effect of the ovarian extract upon the blood pressure is hardly noticeable; if anything, there is a tendency to a gradual, uniform decline, as is shown in the lessening of the force of the heart-beats, and gradual progression towards the abscissa in Fig. 8.

The effect of thyroid extract upon the blood pressure is shown in Fig. 9. There is always a distinct drop; this may be followed by a rise with the onset of a convulsion (see Fig. 9 *continued*).

3. Pituitary Extract.

The extract used was, in this case, also kindly prepared

Fig. 9 *continued*.—Menstruating uterus: effect of thyroid extract. (Reduced about one-half.)

2. Thyroid Extract.

For these experiments we used a solution of thyrocol of a strength of 1 in 10 in normal saline.

(a) There was no effect upon the inactive uterus.

(b) Upon the menstruating uterus the effect of thyrocol was to cause an increase in the strength and number of

Fig. 9.—Note: The contraction marked *c* followed the injection, the uterine marker being a little behind the proper line in this figure and in Fig. 9 *continued*. (Reduced about one-half.)

for us by Mr. H. H. Dale, of the Wellcome Laboratories; 1 c.cm. of the solution contained 0.1 gram of fresh infundibulum. As previously stated (see Paper I), it is only this portion of the pituitary gland which is active in the respect shown here.

(a) Upon the inactive uterus pituitary extract will pro

duce a slight effect. This is shown in Fig. 10, where an evident wave of contraction is seen to occur in a uterus which had not previously contracted.

(b) Upon the menstruating uterus pituitary extract produces a very marked effect, causing much more powerful,

Fig. 10.—Inactive uterus: effect of pituitary extract (0.5 c.cm.). (Reduced about one-half.)

frequent, and prolonged contractions than those occurring normally.

(c) Upon the pregnant uterus the extract produces the same effect as upon the menstruating organ, with the qualification that the contractions are, as always obtains in this condition, more forcible because of the increase in the muscular structure in the walls, and the greater sensitiveness to stimulation which is exhibited during pregnancy. This effect is shown in Fig. 11.

In Figs. 10 and 11 the effect of pituitary extract upon the blood pressure is well seen. There is an immediate and extensive rise. This rise is maintained for a considerable time. In Fig. 10 secondary rises—three in number, with two less important ones—are very prettily shown. These occurred during the act of defaecation, brought about, no doubt, by the effect of the pituitary extract on the intestinal muscles.

Fig. 11.—Pregnant uterus: effect of pituitary extract (0.5 c.cm.). (Reduced about one-half.)

Mr. H. H. Dale also has shown the effect of this extract upon the uterus, using a different method.

4. Adrenal Extract.

The solution of 1 in 1,000 adrenalin prepared by Parke, Davis and Co. was used.

The effect upon the pregnant uterus is well known, consequently we only tried the effect of the extract upon the inactive uterus. The result is shown in Fig. 12. A distinct contraction was produced, together with the well-known rise in the blood pressure. This tracing is, in fact, almost identical with that shown in Fig. 10.

5. Placental Extract.

The preparation used was that kindly supplied to us by Dr. F. E. Taylor, who, with Professor Dixon, has recently published the results of their work with the extract prepared by them from the placenta.

(a) Upon the inactive uterus this preparation, used

Fig. 12.—Inactive uterus: effect of adrenalin (1 c.cm. of 1 in 1,000 solution). (Reduced about one-half.)

according to the instructions of Dr. Taylor, produced quite a marked effect, as is seen in Fig. 13, where two distinct contractions occurred as the result of a single dose.

Fig. 13.—Inactive uterus: effect of placental extract (1 c.cm.). (Reduced about one-half.)

(b) Upon the menstruating organs there appears to be a marked effect. The contractions are prolonged, and recur more rapidly, but their total expulsive force is not increased. This is shown in Fig. 14. It is possible the

Fig. 14.—Menstruating uterus: effect of placental extract (1 c.cm.). (Reduced by one-half.)

dose used (1 c.cm.) was rather small to produce a very decided result. Upon the blood pressure the effect is not at all marked, but there is a slight tendency for it to rise.

(c) Our supply having run short, we did not test the action of this preparation upon the pregnant organ, but in view of our other experiences we have no doubt that powerful contractions would be produced.

6. Uterine Extract.

In order to obtain this extract it occurred to us to use the secretion obtained from the uterus by ligation of the

uterine cornua in rabbits. In this way we obtained, in a concentrated form, the secretion of the glands, and it may be taken for granted, therefore, that such a secretion would resemble in its action an active extract prepared from the whole organ. We found that the most active preparation was that obtained fresh and from a rabbit capable of menstruating. The secretion so obtained was very fatal

Fig. 15.—Inactive uterus: effect of uterine secretion. (Reduced about one-half.)

in its effect unless used dilute. We used it, therefore, in a dilution of 1 to 4: even then we could readily produce fatal effects. Our records only show, of course, those cases in which no bad result, beyond perhaps clotting in the blood-pressure cannula, was produced. We found this secretion the most powerful in its effect upon the uterus of any of the animal extracts used by us.

Fig. 16.—Menstruating uterus: effect of uterine secretion. Note clotting in the blood-pressure cannula. (Reduced about one-half.)

(a) In Fig. 15 is seen the result upon the inactive uterus. There is an immediate and marked contraction, followed by several smaller ones.

(b) Upon the menstruating uterus the effect appears to be that the contractions become prolonged considerably, and occur more frequently.

In Fig. 16 this is well seen, but apparently there is a slight delay in bringing about the result. This, however, may have been due in this case to fatigue.

(c) Upon the pregnant uterus, as one would expect, we obtained a very powerful reaction. The uterus was thrown into a series of violent and continuous contractions. This is seen in Fig. 17. There were no general convulsions, so that the effect appears to be specific.

Uterine secretion appears to raise the blood pressure, but owing to the marked rapidity with which clotting occurred in the cannula no very good tracings of the blood pressure were obtained. There was, however, no general intravascular clotting.

Fig. 17.—Pregnant uterus: effect of uterine secretion. (Reduced about one-half.)

in the calcium content of the systemic blood of pregnant women towards the termination of the intrauterine life of the fetus, and taking into consideration the important part played by the calcium salts in all processes associated with female genital activity (see previous papers), we thought that our work on uterine contractions would not be complete unless we endeavoured to show the effect produced upon these contractions by such an important normal constituent of the blood.

For the purpose of intravenous injection we found that a solution of 0.1 gram in 1 c.cm. of calcium chloride was the best suited to our purpose.

(a) We were unable to produce any effect upon the inactive uterus.

(b) Upon the menstruating uterus a marked effect was produced, as is seen in Fig. 18. From a somewhat weak and prolonged contraction the character was changed so that the expulsive contraction became more powerful and definite, without much loss in the length of the total contraction. We noticed, however, that when the uterus was tired the contraction was apt to be of a more prolonged and tetanic character in addition to being increased in force, and further that the effect was somewhat delayed after the injection. (See Fig. 19.) This delay we frequently noticed when trying the effect of calcium salts upon the uterus.

(c) Upon the pregnant uterus the effect is, as we should expect from our previous observations, very well marked. This is seen in Fig. 20. In some of the tracings obtained the effect was more violent than in the case illustrated.

Calcium salts cause the blood pressure to rise. This, though not nearly so marked as with pituitary and adrenal extracts, is often quite distinct, as is well shown in Fig. 20.

As we have said elsewhere, we have not found that injections of calcium salts cause intravenous clotting.

REMARKS AND CONCLUSIONS.

Such, then, are the results of the investigations which have occupied much of our time and exercised much of our patience. On account of limitations in the former we have not been able to carry out other experiments on the same lines as we had hoped. Some day we may be able to return to the subject; if so, we shall try the effect of extracts made from the whole uterus in order to see if a marketable extract can be made which will have the same definite effects upon uterine contractions as the uterine

secretion has without, possibly, the marked effect of the latter upon the coagulation of the blood, an effect possibly produced by nucleo-proteids.

We should like to test the action of fresh blood from a parturient rabbit upon one less advanced in pregnancy.

7. Calcium Salts.

One of us (W. B. B.) having already observed an increase

Also, if possible, to have discovered some substance circulating in the blood which definitely inhibits uterine contractions.

Our results, then, indicate that all those substances—most of them being extracts prepared from the ductless glands—which we have investigated appear to increase uterine contractions, and that most raise the blood pressure, some much more than others.

We do not know whether it is quite logical to come to such a conclusion, but it seems to us that probably those extracts such as the pituitary and adrenal—we will omit

been found to contain. We have ourselves no first-hand knowledge upon this point.*

Uterine secretion, we venture to think, however, must be specific to some extent, as we have used it straight from the living rabbit to the one under experimentation. Indeed, it seems only feasible that it should have some such action, and the fact that during menstruation, when this substance is being excreted, marked contractions are constantly in progress makes it a fair assumption that these contractions are caused by the direct stimulation of the compound substance we may call "uterin" which

Fig. 18.—Menstruating uterus: effect of calcium chloride (0.1 gram in 1 c.cm.). (Reduced about one-half.)

placental and uterine extracts for the moment—which cause contractions in the inactive uterus act not specifically upon the uterine muscle, but upon involuntary muscle in general. In regard to these, their marked effect upon the blood pressure gives further proof of this.

Of the others, thyroid extract lowers the blood pressure but increases the uterine contractions. In this case, however, the contractions may form part of a general convulsion. Should this occur the blood pressure rises. We think, therefore, that thyroid extract may be dismissed from the competition for specific effect.

Fig. 19.—Menstruating uterus: delayed effect of calcium chloride. (Reduced about one-half.)

Next we have to consider the claims of ovarian extract; and we must confess at once that we wish we had been able to extend considerably our observations in this direction, especially in the matter of using more than one preparation of this organ. We should have liked to note the comparative effect of the extract prepared from rabbits' ovaries during the inactive, menstruating, pregnant, and lactating periods, for we should not be surprised to find different results would be obtained with preparations obtained in the different circumstances. That result in which delay in the contraction of the pregnant uterus occurred is full of significance, and it may be that the ovary of pregnant animals controls uterine contractions, especially in their expulsive effects.

In regard to the secretion obtained from the uterus we were much interested. That it has an effect upon the inactive uterus is undoubted, so that one might be tempted to class it with pituitary, adrenal, and placental extracts. It does not, however, raise the blood pressure in the way that the two first do.

The uterine secretion and placental extract are somewhat similar, then, in their action, and possibly may contain the same substance which effects uterine contractions. We are informed, however, that the specificity of placental extract has been disproved, and that its effects are produced by the products of decomposition it has

is in process of excretion, and which may in some forms exist in the blood.

Finally the calcium salts are shown to exert a definite influence upon uterine contractions, with a slight but definite rise of blood pressure. This action is well illustrated, both upon the heart and upon the uterus. A slow, forcible, and rhythmical contraction is produced—the very type that is seen in labour.

We admit that we have been unable in our experiments so far to show definitely that labour is produced by the action of calcium salts in the blood, but we have gone some way towards this, especially in that we have previously shown (see Paper II) that uterine secretion is rich in calcium salts. Consequently of the various substances used uterine secretion and calcium salts appeared to us to possess most points in favour of specific action.

This question of specificity in the matter of uterine contractions is, then, at once of considerable difficulty and of great importance. We do not think that until the further investigations indicated have been carried out it can be authoritatively stated that one reagent alone is responsible therefore—for the contractions in menstruation and labour.

So far as we have gone we incline to the belief that calcium salts circulating in the blood, or excreted by the

Fig. 20.—Pregnant uterus: effect of calcium chloride. (Reduced about one-half.)

uterus, play the most important rôle in this connexion. At the same time we are alive to the probability that they

*Since writing this we have been favoured with a letter from Dr. O. Rosenheim in which he confirms the above statement. This disposes of the claim put forward by Professor Dixon and Dr. F. E. Taylor in regard to the specific action of placental extract.

may act in conjunction with other substances elaborated by such glands as the infundibular portion of the pituitary, either in a harmonic or conjunctive manner. We feel assured, however, that the secret is not now deeply hidden in view of the observations already made.

Contractions of the Human Uterus.

From our observations upon the uteri of rabbits, we may assume that the contractions of the human uterus are governed by the following circumstances:

First, that the normal non-menstruating, non-pregnant uterus does not contract at all. Secondly, that the menstruating uterus is in a state of constantly recurring expulsive contractions. And thirdly, that the normal pregnant uterus contracts and relaxes in a complementary fashion, no expulsive force being exercised; but that during labour violent expulsive contractions occur.

Therapeutics.

In regard to any therapeutic suggestions we might make we feel that the subject is too big and too uncertain to do justice to here, so that we will content ourselves with one or two remarks only. Until a satisfactory uterine extract is upon the market or the specific (?) calcium salt synthesized, we think that we have a very efficient therapeutic product in the pituitary extract, which we have reason to believe Messrs. Burroughs and Wellcome will shortly put upon the market in hypodermic form. We have ourselves used this preparation clinically with satisfactory results. A dose of 2 c.cm. of the infundibular extract (0.1 gram in 1 c.cm.) should be given hypodermically and repeated if necessary. In addition to the effect upon the uterus it is most valuable in cases of shock in which the blood pressure must be raised, the protracted period during which the pressure is kept up adding considerably to its value.

We also think that it might be used in the place of physostigmine in paralytic distension of the bowel, its action upon the intestinal muscle being well shown in Fig. 20.

Lastly, we would call the attention of physicians to the effect of the calcium salts upon the heart as shown in the series of tracings made by us for Sir James Barr's paper on Mitral Stenosis (see BRITISH MEDICAL JOURNAL, December 19th, 1908, p. 1797). It appears to us that where it is necessary to slow the heart and strengthen the heart beat, calcium salts administered hypodermically or intravenously should form an ideal drug. In further connexion with this point our remarks on exophthalmic goitre in Paper I may be referred to.

While much remains to be learnt in regard to many of the problems upon which we have endeavoured to throw some light, we hope that the results we have already obtained, and summarized in these four papers, will not only justify the time, thought, and labour expended upon them, but also induce others to complete and extend the work we have so imperfectly performed in the much-neglected branch of gynaecological physiology.

AN exhibition of flying machines and internal combustion engines intended for use in connexion with the same has been open at Olympia during the current week. It was promoted by the Society of Motor Manufacturers in conjunction with the Aero Club, and of the exhibits several were duplicates of machines which have already proved their capacity for actual flight and the carrying of passengers. Others were as yet in the model stage, and though they exhibit extreme ingenuity more perhaps is expected of them by their inventors than by any one else. Of the engines, a good many seemed to be the work of firms—such as the Wolseley Tool and Motor Car Company—whose names are already familiar in connexion with automobiles. The holding of this exhibition is an event worth noting as being the first of its kind. Otherwise the exhibition was not of special interest to medical men, as flying is not yet sufficiently popular to necessitate a new entry in the indexes of text-books on surgery on the lines of "golf elbow," "tennis wrist," or "back-firing fracture." Doubtless, however, such entry will presently appear—in connexion with the cervical vertebrae.

THE THERAPEUTIC COMMITTEE OF THE British Medical Association.

REPORT ON

THE LOCAL ANAESTHETICS RECOMMENDED AS SUBSTITUTES FOR COCAINE.

By C. N. LE BROcq, B.A., M.D.

(From the Pharmacological Laboratory, Cambridge.)

THE substances which have been investigated are: Stovaine, novocain, tropacocaine, beta-eucaine, alpin, beta-eucaine lactate, nirvanine, holocaine hydrochloride, acaine, orthoform (new), anaesthesine.

The points to which special attention has been paid are those laid down by Professor Braun as essential in estimating a local anaesthetic action. They are:

1. A lower degree of toxicity than cocaine in proportion to its local anaesthetic power.
2. Sufficient solubility in water. The solutions should be stable, that is, they should keep without deterioration and be capable of sterilization by boiling.
3. Absence of any sign of irritation. There should be no injury to the tissues; the local anaesthetic should be easily absorbed without causing any after-effects, such as hyperaemia, inflammation, infiltrations, or necroses.
4. Compatibility with adrenalin.
5. Rapid penetration of the mucous membrane, and suitability for medullary anaesthesia.

The only exception I would make to these postulates of Braun is that dealing with absorption. It is not obvious that easy absorption is desirable. If the drug is absorbed slowly it remains longer in contact with the nerve fibrils, and produces a more prolonged action. It has been stated that by delaying absorption, as by local vaso-constriction, we are giving the anaesthetic a longer time for action, and it is for this reason that adrenalin is injected with these substances.

If a drug can be obtained which fulfils the above conditions it can be safely said that it will supersede cocaine.

To arrive at a satisfactory conclusion it is necessary to deal with each drug separately, and to discover how closely each approaches the conditions specified by Braun.

Solubility in Water.

Solubility in water is essential for subcutaneous and intraspinal injections. If a drug is not soluble in water to the extent of forming a 2 per cent. solution, I have regarded it as unworthy of competing with cocaine. By examining the solubility of these drugs, the list is considerably diminished, for acaine, holocaine hydrochloride, anaesthesine, orthoform (new), beta-eucaine, are all more or less insoluble, and for this reason alone unsuitable for producing local anaesthesia by injection. Beta-eucaine is not completely soluble in cold water to the extent of forming a 2 per cent. solution, but if the solution is warmed a 2 per cent. solution is readily obtained. As dusting powders, these drugs may, of course, still prove useful, but I am not here concerned with that point.

Cocaine, stovaine, novocain, tropacocaine, beta-eucaine lactate, alpin, and nirvanine are freely soluble in water; their solutions are stable, and as a 2 per cent. solution they will keep for a short time without deterioration.

Sterilization of Solutions.

Cocaine cannot be boiled, as decomposition occurs, and the drug loses its activity and is gradually destroyed. Stovaine, novocaine, beta-eucaine lactate, tropacocaine, alpin, nirvanine can be sterilized at 115° C. if necessary, undergo no change, and the drug is as active after as before sterilization.

Local Anaesthetic Properties.

The determination of the local anaesthetic action is not easy, as it is not practicable to work with accuracy on the lower animals on account of the difficulty in determining when sensation is absent or merely blunted. The method

I adopted was to take cocaine as the standard and to compare each drug with it separately.

By numerous experiments on frogs, rabbits, and human beings, which will be described in detail elsewhere, I arrived at the following conclusions:

Stovaine has a more powerful anaesthetic action, weight for weight, than any of the other local anaesthetics. Alypin, beta-eucaine lactate, novocain, and tropacocaine have anaesthetic properties about equal to cocaine. Nirvanine as a local anaesthetic is inferior to cocaine.

Toxicity.

Having determined the relative anaesthetic action, it remained to estimate the toxicity of these drugs. The method employed was to find the minimal lethal dose—the smallest dose which will kill the animal—in frogs, mice, and rabbits.

All these drugs produce death by paralysing the central nervous system in mammals and the heart in frogs. When a toxic dose of a drug is injected into a frog, movements gradually cease; the animal soon lies still in any position in which it is placed, and becomes to all external appearances dead; respiration ceases, and there is no response to any sort of stimulus. If the dose has not been large enough to paralyse the heart, it continues to beat, and as soon as the effects of the drug on the nervous system pass off the frog recovers. The explanation of the recovery is, of course, that a frog can exist for a considerable time, even for many hours, without respiration. Thus in obtaining the minimal lethal dose in frogs it is necessary to give these drugs in doses which not only paralyse the nervous system, but which are large enough to paralyse the heart also.

Therefore the minimal lethal dose in frogs represents the action of the drug on the heart, and in mammals its action on the central nervous system.

Toxicity in Frogs.

The minimal lethal dose for a 20-gram frog, using a 2 per cent. solution, is for:

Alypin	6 minims (most toxic)
Cocaine	32 "
Stovaine	15 "
Nirvanine	17 "
Beta-eucaine lactate	20 "
Tropacocaine	20 "
Novocain	40 " (least toxic)

Toxicity in Mice.

The minimal lethal dose for a 23-gram mouse using a 2 per cent. solution, is for:

Alypin	4 minims.
Cocaine	5 "
Nirvanine	7 "
Stovaine	8 "
Novocain	10 "
Tropacocaine	10 "
Beta-eucaine lactate	12 "

Toxicity in Rabbits.

The minimal lethal dose for a rabbit weighing 1,000 grams, using a 10 per cent. solution, is for:

Alypin	...	between 18 and 23 minims.
Cocaine	...	" 24 " 30 "
Stovaine	...	" 35 " 45 "
Tropacocaine	...	" 44 " 54 "
Novocain	...	" 53 " 63 "
Beta-eucaine lactate	...	" 65 " 75 "

As the toxic action of these drugs is to paralyse the nervous system, and so the respiratory centre, the toxicity in mammals must be regarded as the correct reading, for when respiration ceases the animal dies.

If the toxicity of Cocaine be represented as 1, then

The toxicity of Alypin	...	will represent 1.25
" " Cocaine	...	" 1.0
" " Nirvanine	...	" 0.714
" " Stovaine	...	" 0.625
" " Tropacocaine	...	" 0.500
" " Novocain	...	" 0.490
" " Beta-eucaine lactate	...	" 0.414

Conclusions from the Above.

Alypin has anaesthetic powers equal to cocaine, but a higher toxicity, and so does not comply with the condition enunciated by Braun. Nirvanine has not the anaesthetic power of cocaine, and it is only slightly less toxic. As, however, we have four drugs equal to or stronger than

cocaine in anaesthetic power, and considerably less toxic than nirvanine, no further experiments with this drug were deemed necessary.

From this it will be seen that only four drugs, namely, stovaine, novocain, tropococaine, and beta-eucaine lactate, have complied with the first two conditions. With these four drugs further experiments were performed to discover how they fulfil the other conditions laid down for the "perfect local anaesthetic."

Irritant Action on the Tissues.

Very little is known of the action of the local anaesthetics on the tissues with which they come in contact. This effect is, however, extremely important, for it has been stated that gangrene and sloughing of the tissues have followed the use of certain of these drugs. It is well recognized, however, that they are all general protoplasmic poisons, that whilst having a special predilection for nervous structures they depress and ultimately destroy every form of living tissue.

In these, as in previous experiments, cocaine was taken as the standard. Cocaine is generally recognized as having a slight irritant action on the tissues, and occasionally, after instillation into the eye, produces considerable conjunctivitis.

For these experiments rabbits weighing about 1 kilogram were used. The abdomen was shaved and the skin washed and made aseptic, after which 10 minims of a 10 per cent. solution of the drug was injected subcutaneously. The drug was carefully sterilized, and all antiseptic precautions were observed.

After injection the part was kept under immediate observation for several hours, and then inspected daily for one week more.

Cocaine caused slight swelling and hyperaemia soon after the injection. The part completely recovered.

Stovaine caused intense hyperaemia and dilatation of the blood vessels, followed by sloughing of the part.

Beta-eucaine lactate caused swelling and thickening about the seat of injection, followed by sloughing.

Tropacocaine caused swelling and some thickening, followed by sloughing.

Novocain showed no swelling and no hyperaemia. The part was perfectly normal after injection, and remained so.

In the above experiments, where sloughing and necrosis occurred there were no signs of pus formation.

It is seen that a comparative investigation into the action of these drugs on the general tissue is of the utmost importance, for most of them possess a decided irritant effect; so much so, that they will produce sloughing and necrosis of the tissues with which they come in contact.

A 10 per cent. solution is a stronger solution than is generally used therapeutically, yet this strength is still employed; moreover, 10 minims of a 10 per cent. solution roughly represents 1 grain, a quantity which is far exceeded when weaker solutions are injected. And even if it be objected that it is not fair to infer from a 10 per cent. solution what will occur in a strength of 1 per cent. or 2 per cent., yet the present experiments still show the relative irritant action of these drugs. A drug which is only mildly irritant as a 1 per cent. solution, will presumably be the more irritant as a 2 per cent. solution, until, as the strength is increased, a stage is reached when destruction of the tissues and necrosis is obtained.

The irritant action of stovaine, beta-eucaine lactate, and tropacocaine is far greater than that of cocaine; novocain is the only drug which is superior to cocaine in this respect.

Compatibility with Adrenalin.

All the local anaesthetics are compatible with adrenalin if the solutions are fresh and kept only for a short time. After a day or two the adrenalin decomposes unless it is kept in stoppered opaque bottles.

CONCLUSIONS.

In determining which of these four drugs is the most suitable substitute for cocaine, it is necessary to compare them with one another.

If novocain and tropacocaine be first compared, their toxicity and anaesthetic properties are, roughly, equal; but the irritant action of tropacocaine is far greater than that of novocain; in other respects their actions are similar,

therefore novocain is a more suitable drug than procaine.

On comparing novocain with beta-eucaine lactate it is seen that while the anaesthetic value is roughly about equal, the toxicity of beta-eucaine lactate is slightly less than that of novocain, but the irritant action of beta-eucaine lactate is far greater than that of novocain. It appears, then, that while beta-eucaine lactate has only a slighter degree of toxicity to recommend it in preference to novocain, its irritant action far and away overshadows any such slight advantage, and novocain is recognized as undoubtedly the better drug of the two.

Finally, it only remains to compare novocain with stovaine. The former drug is less toxic and much less irritant; indeed, its specific action on nerve fibres is so great that it has practically no destructive effect on the other tissues; stovaine is more toxic and considerably more irritant.

The one definite advantage which stovaine possesses over all the other local anaesthetics is its greater injurious action on nerve fibres, as shown by anaesthesia. Nevertheless, the specific action of stovaine on nerve fibres is less than that of novocain, since stovaine destroys other tissues besides nerve fibres. If stovaine and novocain be given in doses so that their anaesthetic action is the same, both the irritant and toxic effect of the former drug, even in the smaller dose in which it is administered, are greater than the relatively larger doses of the latter.

I come to the conclusion, therefore, that of the drugs which have been investigated, novocain is most satisfactory for general use. Its anaesthetic action is equal to that of cocaine, and its toxicity and general destructive power on the tissues are very much less.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

ACUTE YELLOW ATROPHY OF THE LIVER.

ON account of the rarity of the disease, the following notes on a case of acute yellow atrophy of the liver, which was under treatment at the Royal Naval Hospital, Portland, may be of interest:

D. L., aged 19, Private R.M.L.I. (Channel Fleet), was admitted to Portland Hospital on February 19th, 1909. He had been sick on board his ship since January 12th suffering from jaundice, which the man himself attributed to a chill caught from sleeping in a damp hammock.

On admission the signs and symptoms were at first obscure, and, during the earlier period of his illness, indistinguishable from an attack of catarrhal jaundice. Gastro-intestinal symptoms were well marked, the tongue was covered with a white fur, and there was anorexia, and occasional vomiting of partly digested food, with a little bile-stained mucus. Once, on January 29th, he had "coffee grounds" vomit. The bowels were constipated, and the stools pale and clay-like. From first to last he was deeply jaundiced, but this became more pronounced toward the end. The temperature all through was sub-normal. The pulse was slow at first (about 64), but during the last few days became very quick (130).

The liver was markedly diminished in size, liver dullness only measuring about 1½ in. vertically in the anterior axillary line. The urine contained much bile, and crystals of tyrosin were present in abundance; of leucin in very scanty numbers.

On February 3rd (twenty-two days after the onset of the jaundice) cerebral symptoms set in: headache was now very severe, with drowsiness, apathy, and side-to-side movements of the head. He soon lapsed from a semi-unconscious condition to a state of more or less deep coma, the pupils being widely dilated and not reacting to light; urine was passed under him. While in this condition the patient cried out loudly from time to time, tossing the head from side to side. The cry was typically meningeal. He gradually sank and died on February 8th.

At the necropsy the liver was much diminished in size, only weighing 28 oz. The capsule was wrinkled, and on section the liver was of a markedly yellow colour, with in

many places patches of bright red. The bile ducts were empty, as was also the gall bladder. Petechiae were found on the pancreas, kidneys, and great omentum. The spleen weighed 7 oz., and was normal on section. The kidneys each weighed 7 oz.; the cortex was a little congested. Sections of the liver showed the usual degenerative change on microscopic examination, and an extract showed crystals of leucin. A bacteriological culture from the liver on blood serum for sixteen hours at 37° C. showed Gram-negative diplococci in almost pure culture.

H. M. BRAITHWAITE,
Surgeon, R.N. Hospital, Portland.

LACERATION OF ABDOMINAL WALL, WITH PROLONGED PROTRUSION OF INTESTINE: RECOVERY.

LACERATIONS of the abdominal wall, accompanied by opening of the peritoneal cavity and protrusion of a viscus, may be reasonably considered accidents of extreme gravity, and the gravity is proportionately increased by the length of time a viscus has been protruded, and the conditions to which it has been exposed. The recent publication in the BRITISH MEDICAL JOURNAL of a case of this description suggests the recording of the following interesting instance.

On February 10th, 1906, a native who had been gored by a cow was admitted to the Swedish Mission Hospital. The patient was accompanied by his master, who told the following story: At 6 a.m. on the same day the injured native had let the cattle out of the kraal, and, while standing in the gateway, had been deliberately gored by a passing cow. The abdominal cavity was opened, and a large loop of intestine protruded. His master, who was present, at once replaced the intestine, fastened a broad calico binder round the abdomen, and brought the patient into hospital by the first available train. He arrived at 11.50 a.m., in very fair condition, and was attended to immediately. On opening the binder I was dismayed to find a large mass of small intestine intimately mixed with and adherent to the binder and to a very dirty blue calico shirt, and all cemented together with dried blood. Under continuous irrigation with hot boric solution I proceeded to separate the adherent mass by the aid of gauze sponges, and in doing this unavoidably stripped extensive areas of peritoneum from the intestine. This proceeding occupied two hours and twenty minutes, and only at its completion was I in a position to ascertain the actual conditions present. Fully 8 ft. or 9 ft. of distended and deeply congested small intestine were lying on the abdomen. The intestine was studded with particles of cow manure, grit, and dried blood, the removal of which was hopeless. The abdominal wound, irregularly circular, and about 2 in. in diameter, was situated 2 in. to the left and a little below the level of the umbilicus, and was blocked by the mesentery which had been drawn through the orifice by the protruded intestine. Up to this point the patient had not complained of much pain, and did not require chloroform, but now, as enlargement of the wound was necessary in order to return the distended intestine, this was administered, the wound enlarged about 2 in. upwards, the intestine returned, and the abdomen closed with three layers of sutures. The entire operation had lasted from 12 noon until 3 p.m., and the intestine had been outside the abdomen for approximately eight and a half hours. For three days the patient was kept under the influence of opium; on the third day the bowels acted with the aid of a soap and water enema; the wound healed by first intention: there was no rise of temperature, and he was discharged on the fourteenth day. I saw this man about six months afterwards, when he complained of abdominal pain after eating meat, otherwise he was in good health.

The interest of this case lies in the quantity of intestine protruded, the duration of the exposure, the exceptionally septic conditions, the unavoidable stripping of large areas of peritoneum, the return of the bowel studded with particles of organic matter, and the unexpected and uneventful recovery of the patient.

I have much pleasure in acknowledging the assistance I received in this case from Sister Gustava Perowne and Sister Amanda Skroog of the Swedish Mission Hospital.

Reports of Societies.

MEDICAL SOCIETY OF LONDON.

Monday, March 22nd, 1909.

CHARLES BARRETT LOCKWOOD, F.R.C.S., President, in the Chair.

Coroners and Medical Men.

MR. WALTER G. SPENCER, in opening a discussion on the relationship between coroners and medical men, said that the difficulties which had arisen between coroners and medical practitioners were due to many inherent causes, such as the difference in the education which formed the legal as distinguished from the medical mind, and which often made it so difficult to find a common ground upon which to argue. Moreover, there were the entirely different objects which the law had in view when the cause of a person's death was under consideration. The legal mind was fostered on authority and tradition, two ideas absent and even inimical to the medical mind of the present day, but the law, in spite of itself, was becoming more and more immersed in the flood of modern science and medicine. Death certification depended on medical nomenclature, upon medical nomenclature was based medical statistics, and upon medical statistics were built up the policies regarding public health and preventive medicine which constituted the most satisfactory work of modern statesmen. The correct findings as to the cause of death were linked up with the best Acts of Parliament. If one plunged into the middle of the subject one came at once upon that hoary institution—the coroner's jury, which public superstition held to be the supreme arbiter of facts, whilst it was evident that, to a very large extent, the members comprising the juries were ignorant of the meaning of the words they heard and used. It was needless to discuss verdicts arrived at by juries in the absence of *post-mortem* examination, or, it might be, without even a statement from the well-informed practitioner who had been acquainted with the case throughout. Under such circumstances the conclusions arrived at must be merely presumptive in character, and the medical profession could not be expected to regard those verdicts; also, from the point of view of modern public health legislation, statistics so registered might be erroneous. The recent Children Act was highly to be commended, but verdicts at inquests involving questions as to overlying, stillbirth, and infanticide were of no value for statistics in the absence of *post-mortem* examination. It was obvious that, whenever possible, necropsies must be carried out by those persons who had special knowledge and experience, for it was not a question of demonstrating one likely cause of death, but at any autopsy other points connected with and affecting public health might be laid bare. It followed, therefore, that advantage must be taken of special pathologists, such as were already connected with their hospitals, and who formed the nucleus of a body of men best fitted to draw up a preliminary report for a coroner arranging to hold an inquest; such a report would be a helpful guide to him when considering the best witnesses to call. Supposing the coroner chose to hold an inquest on every case of death, whether the result of operation, anaesthetic or other causes, there could be no valid objection, always providing that it was preceded by a *post-mortem* examination made by a competent pathologist. Indeed, if a *post-mortem* examination were made in every medical case there would be a likelihood of some interesting and useful finds, even more often than in the cases just mentioned. Of course the pathologists employed must be the genuine article. If the medical profession declared that a *post-mortem* examination by a skilled pathologist was the necessary preliminary to every inquest, then it might well leave the coroner and those members of the public concerned to settle when these should be held. A question of considerable complexity was that of the right and proper practitioner to be called to give evidence—there was the practitioner who had always attended the deceased, the one who had occasionally done so, the one who was called in just before death, or after death had occurred; there was the practitioner who saw the accident and the one who arrived upon the scene shortly after; also the house-surgeon at the hospital where the patient died.

By receiving an early report from the pathologist the coroner would be much assisted in the selection of witnesses to be called, and it could not then be said that he was guided in the matter by hearsay evidence picked up by the coroner's officer, or that he was prevented by prejudice from calling upon those who had treated the case in life.

Dr. LOVELL DRAGE said that in the country districts the present machinery of coroners' courts was perfectly suitable for the purpose. He thought that the rule in regard to "viewing the body" should be retained, but that the coroner should have discretionary powers in the matter.

Dr. F. J. SMITH said that a person should not be appointed a coroner unless his name was on the *Medical Register* and in the *Law List*. A suggested alteration in regard to certificates of death was that a medical man called upon to certify a death should, after seeing the body, either state fully the fact and cause of death, with such other information as might be required by law, or notify the death to the coroner on a separate form, and that such certificate or notification be paid for. He also advocated the holding of a preliminary inquiry by the coroner, in which investigation the results of *post-mortem* examinations should be considered. He further held that *post-mortem* examinations should be made by experts in this work. England might be divided up into twenty districts, and to each district there should be appointed a special pathologist.

After Mr. R. GILL had discussed the question from the point of view of the chloroformist, and Dr. BRNSTEIN had spoken, Mr. KELLOCK observed that if the coroner would give more attention to the difficult position of the medical man in giving evidence, and medical men would remember the onerous position and responsibility of the coroner, the relations between them would be more amicable. If a skilled preliminary inquiry were held into the cause of death, it would obviate the necessity of holding many inquests.

The CHAIRMAN said that throughout the country the coroners treated medical men with great courtesy and kindness and with every possible consideration, and only in a few cases the powers of the coroner had been occasionally exercised in an arbitrary and inconsiderate manner.

Mr. SPENCER, in reply, emphasized the point that the legal knowledge of the coroner must be constantly reinforced by the evidence of a specialist in pathology.

MANCHESTER MEDICAL SOCIETY.

Wednesday, March 3rd, 1909.

Mr. W. COATES, President, in the Chair.

Melancholia and Extradural Abscess.

Dr. J. ARNOLD JONES described the case of a spinster, aged 50 years, who was seized with symptoms of melancholia in October, 1907, and was sent to a private asylum in December, 1907. In February, 1908, she had acute auricular pain, apparently due to external otitis. This was treated by incision: copious discharge of pus followed and continued, but the mental symptoms rapidly cleared up, and in this respect she was quite well by May, 1908. In June, during the performance of a radical mastoid operation, a fistula was found leading to the sigmoid groove. Complete recovery followed.

Incontinence of Urine.

Mr. A. E. BARCLAY, in a paper on the electrical treatment of incontinence of urine in adult females, said the object of the treatment was to induce the sensation of the desire to pass water which the patient had to withstand—that is, to educate the brain centre to a sense of its responsibility for the action of the lower automatic reflex. One electrode was placed and moved to and fro past the sphincter, the other below the back. Of possible currents the sinusoidal was preferred. One severe case, a girl of 19, with both nocturnal and diurnal incontinence, on whom all other methods had failed, went into service after three months of treatment, and, after the lapse of a year, wrote to say that she had only been troubled once since she was under treatment.

Pleural Effusions.

Dr. R. W. MARSDEN, dealing with the treatment of apparently acute primary pleural effusions, said that too

much attention was commonly paid to the question of pleuritic adhesion occurring, and relatively too little to the condition of the compressed or contracted lung. Perhaps in a majority of cases the lung might regain complete expansion on withdrawal of fluid after a period of three weeks' compression; but when the temperature was maintained beyond the usual period without evidence of absorption it was advisable not to wait so long before tapping. To ensure complete expansion, as much of the fluid should be withdrawn as would be obtained without untoward signs or symptoms. Replacement of the fluid removed by sterile air was likely to increase the risk of having subsequently to deal with permanent contraction of the lung. If steady absorption did not follow the first tapping, the operation should be repeated at intervals, so long as expansion of the lung could be obtained. A period of two weeks was the maximum during which one should allow compression of the lung, whilst waiting for absorption of the fluid.

Dermatitis Artefacta.

Dr. G. H. LANCASHIRE, in a paper on dermatitis artefacta, pointed out the varying lesions which simple friction could evolve in a hysterical subject. In treating these cases the patient's secret should usually be kept from the knowledge of the rest of the family.

ROYAL SOCIETY OF MEDICINE.

PATHOLOGICAL SECTION.

Tuesday, March 16th, 1909.

Mr. S. G. SHATTOCK, President, in the Chair.

Portal Thrombosis.

Mr. T. W. P. LAWRENCE and Mr. H. CURTIS recorded a case of portal thrombosis in a case in which urethrotomy had been performed. The record was of interest in connexion with the pathology of portal thrombosis, especially as, being actually associated with operative measures, it might have been classed with cases of post-operative thrombosis, so well known to occur after abdominal, and even more frequently pelvic, operations. The *post-mortem* and microscopic evidence proved, however, that the portal thrombosis resulting in occlusion more or less complete, and fatal by hæmatemesis twenty-three days after admission, preceded by a considerable time the urethrotomy performed under local analgesia, there being found long-standing chronic pyelophlebitis but no cirrhosis of the liver. The cause of the pyelophlebitis was sepsis arising from the urethral disease.

The Pathology of the Spleen.

Mr. L. S. DUGGON and Dr. W. O. MEER recorded an investigation which consisted in a histological and bacteriological examination of the spleens of 87 subjects. The cases comprised examples of various acute and chronic infective and non-infective diseases. Out of 7 cases of pernicious anaemia streptococci were grown on only one occasion, and in this instance the patient had died with acute lobar pneumonia. In some instances streptococci and staphylococci were obtained in cultures from spleens which showed no excess of inflammatory leucocytes on histological examination. In the majority of instances of acute infective diseases the finely granular polynuclear cells were present in film preparations in excessive numbers. Endothelial cells were increased in numbers in most instances of acute bacterial infection. Nucleated red cells, both normoblasts and megaloblasts, were found in cases where anaemia was present during life.

Bence-Jones Protein.

Dr. F. PARKES WEBER and Dr. J. C. G. LEDINGHAM described the histology of a case of "myelomatosis" in a woman aged 65 years. At the *post-mortem* examination the bones examined were found converted into hard bony shells filled with a dark-red, opaque, jelly-like substance, and (in the case of cancellous bone) with the remains of cancellous tissue. The jelly-like substance in question was seen on microscopic examination to consist of plasma cells. In many of the cells the nuclei were in process of disappearing (karyolysis), and the cytoplasm contained spaces filled with a substance probably allied to, or an antecedent of, the Bence-Jones protein excreted during life in the urine. Good bony union was found to have

occurred at the site of a fracture of the humerus, which the patient sustained a few months before her death.

A communication upon tumour-like formations of fat, by the PRESIDENT, was taken as read.

MEDICAL SECTION.

Tuesday, March 23rd, 1909.

Dr. T. H. GREEN, Vice-President, in the Chair.

Auto-inoculation in the Treatment of Disease.

Dr. E. C. HOLT read a paper on auto-inoculation versus hetero-inoculation in the treatment of established infective disease, in pyrexial and in apyrexial conditions, as controlled by clinical observation and the estimation of the antitryptic index. Its purport was to submit that auto-inoculation afforded, with certain restrictions, a valuable and rational basis of the treatment of established infective disease, whether fever was present or not, mainly because its aim was the restoration of immunity against the action of enzymes and toxins, from damaged tissue cells in addition to those from bacteria, and that inoculation by tuberculin and other vaccines (hetero-inoculation), though of undoubted value, was not necessarily the best available treatment of such disease, inasmuch as its aim was solely confined to restoration of immunity to the action of bacterial toxins and entirely ignored the factor of non-bacterial enzymic infection. He endeavoured to show by illustrative cases that estimation of the antitryptic index afforded, in conjunction with clinical observation, a reliable gauge of response to immunization procedures of both kinds. By the term "antitryptic index" was meant the relation of the antitryptic power of pathological blood to that of normal blood. Dr. D. LAWSON said that in his experience there was no relation between the temperature curve and the opsonic index; in some cases even the pulse-rate was a better guide to progress of intoxication. Dr. F. PARKES WEBER alluded to the value of regular open-air exercise as a prophylactic against tuberculosis and in the way of producing autoinoculation from the very commencement of a comparatively trivial focus.

SECTION OF DISEASES OF CHILDREN.

At a meeting on February 26th, Mr. SYDNEY STEPHENSON in the chair, the following were among the exhibits: Mr. W. M. MOLLISON: A child of 2 years with *Absent abdominal muscles*. The abdomen was very pendulous and the walls thin and lax, the intestinal viscera being easily felt even when the child cried. The bowels kept regular, and there was no difficulty in micturition. No electrical response could be obtained from the abdominal wall. There did not appear to be any distension of the bladder or thickening of the ureters. Dr. LANGMEAD said that there were about 18 cases on record. Usually there was much distension of the bladder and thickening of its walls with palpable ureters. He believed that most of the cases had died in early infancy; the present one was an exception in that respect. Dr. O. GRÜNBAUM: A case of *Hirschsprung's disease*, or chronic dilatation of the colon. A child, aged 4 years, was admitted to hospital in August, 1908, for fits and constipation. The abdomen was enormously distended, the skin being tight and the superficial veins prominent. On administering an enema an enormous result was obtained, and on repeating this at intervals the child returned to a normal condition. He has been readmitted twice since with a similar condition. Improvement followed rapidly each time upon the administration of enemata. The risk of colectomy was so great that the exhibitor, having consulted with his surgical colleague, considered that so long as the child could be kept in a healthy condition with suitable treatment no operation should be done. Dr. G. A. SUTHERLAND said that all the cases he had seen had died. As the prognosis was so bad and the patient was now in such a favourable condition it would be well to operate now. Mr. LOCKHART MUMMERY said the mortality of colectomy in a number of cases in this condition which he had collected was 75 per cent. The only operation likely to give permanent results was excision of the dilated portion of the colon. This was a serious proceeding, but even if successful the colon might become redilated. He quoted four cases in which this had occurred. In a case which had gone on to adult life—a man, aged 23—he had done appendicostomy, the bowel being washed out daily.

It was now six months since the operation, and the man had had no obstruction. The meeting ended with a discussion on the medical examination of school children.

OTOLOGICAL SECTION.

At a meeting on March 6th, Dr. PETER MCBRIDE, President, in the chair, Mr. SYDNEY SCOTT, in a paper entitled *The Problem of Vertigo*, gave an account of an investigation of nystagmus and eye movement associated with giddiness in a large number of patients with diseases of the ear. He had adopted the caloric and rotation tests introduced into clinical otology by Robert Bárány, and had had opportunities of testing cases both before and after the internal ear had been destroyed by disease or operation. Various forms of nystagmus were recognized and the labyrinthine type fully described, together with the author's views of its mechanism. He had found on completion of his research, which extended over a long period, that his observations confirmed those of Mach, Breuer, and Bárány; he presented some new hypotheses to explain the phenomena observed. Some new data were presented in connexion with so-called ablation nystagmus—that is, persistent nystagmus of true labyrinthine type after removal of one labyrinth, the other labyrinth being normal. The author asserted he had been able to arrest this form of nystagmus by compression of the common carotid artery. The mechanism of the stimulus was accounted for on the assumption of impaction waves from the internal carotid artery in the carotid canal being transmitted to the labyrinth and ampullary apparatus of the semicircular canals. The hypothesis was put forward with a number of facts supporting it, and the author submitted that if his observations could be substantiated by competent observers, the hypothesis would have a much wider application than he had dealt with in his communication. The paper was illustrated by serial sections of the human labyrinth displayed by the epidiascope. A demonstration was given of glass models representing the human membranous semicircular canal and utricles. In the discussion which followed, Sir VICTOR HORSLEY said that in Mr. Scott's investigations and views he perceived a new basis for considering some of the many obscure features of vertigo. His own observations on monkeys were substantially confirmed by Mr. Scott's work on the labyrinth in children. In apes certain forced movements of the head followed operations on the labyrinth. He hoped Mr. Scott would give an account some time of head movements associated with nystagmus in human subjects.

THERAPEUTICAL AND PHARMACOLOGICAL SECTION.

At a meeting on March 2nd, Dr. CECIL WALL, in opening a discussion on *The treatment of spasmodic asthma*, said that in few diseases had theory played so large a part. There was little unanimity, save on the one point that during an attack the bronchial tubes were diminished in calibre, and that this diminution was probably effected through the agency of the central nervous system. Environment, the climate, and general hygiene were all important in preventing attacks. He had notes of 23 cases of asthma associated with definite nasal defects. After suitable treatment to the nose, in 14 there was marked improvement. In none was complete cure recorded. Of symptomatic remedies he had found most useful potassium iodide, arsenic, and stramonium. Of the last, the extract was better than the tincture. The pharmacopoeial dose was excessive, yet it should be given in doses sufficient to cause slight toxic symptoms. Most patients showed toxic symptoms on taking $\frac{1}{4}$ grain in twenty-four hours. Morphine was very valuable, but the fear of narcomania forbade its frequent use. Professor DIXON illustrated by tracings the supposed etiology of the disease and the action of drugs in inhibiting the spasm. For the production of an attack two things were necessary—a "neurotic" medulla, and a peripheral stimulus as the exciting cause. Dr. HERTZ emphasized the importance of urging the patient to combat the tendency by an exercise of will power. In his own case an attack could often be greatly lessened if he resolutely persisted in pursuing some mental work requiring complete concentration of mind. Dr. SERRIOS referred to details of 40 of his own cases. He found that patients who were entirely free between the attacks offered a prospect of successful treatment, whilst

those in whom the severe attacks altogether subsided giving place to a chronic dyspnoeic condition, were difficult to treat. It was surprising what benefit followed attention to simple hygienic measures, such as the abandoning of an evening meal, regular action of the bowels, and avoidance of fatigue. He had seen relief follow nasal treatment, and the reverse. In one case a series of most severe attacks were precipitated by the removal of polypi. It was important to recognize the neurotic form of asthma, in which the entry of air into the chest was not really impeded, as the superficial aspect of the patient almost exactly resembled asthma. He had also seen good results from respiratory exercises. For the relief of more severe attacks he had had good results with the injection of $\frac{1}{100}$ grain of atropine repeated in an hour if necessary. Dr. CARMALT JONES said he had recently isolated a micro-organism, which he believed to be the cause of certain cases of asthma. He had prepared a vaccine, and in many cases had seen great improvement in the dyspnoea. Dr. GRAY DUNCANSON emphasized the importance, especially in the young, of prescribing a course of breathing exercises, thoroughly carried out and supervised. Dr. CECIL WALL replied.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

Friday, March 5th, 1909.

Dr. E. H. TWEEDY, President, in the Chair.

Fibro-cystic Myomatous Uterus.

Dr. ALFRED SMITH exhibited a large fibro-cystic myomatous uterus, taken from a patient 38 years of age. She had never felt any inconvenience up to some months before her admission to hospital, when she noticed she was getting rather stout. She was sent to him with a provisional diagnosis of ovarian cyst, and the clinical features were identical with the phenomena obtained in that condition. On opening the abdomen he thought he had to deal with an ovarian cyst, but found a fibromyoma which had undergone the degeneration seen in the specimen, giving a uniform pearly whiteness.

The President said the specimen illustrated the difficulty of gynaecological diagnosis. A big fibro-cystic tumour was indistinguishable from ovarian cyst in a great number of cases. In examining per the rectum they could occasionally feel an ovarian pedicle, and if it was absolutely distinguished the diagnosis of ovarian cyst was made, but the absence was no proof that they were not dealing with an ovarian cyst.

Dr. SMITH, in reply, said he did not make any rectal examination, as the case seemed perfectly simple and straightforward.

Cyst of Gaertner's Duct.

Dr. ALFRED SMITH exhibited a uterus with large cyst of Gaertner's duct attached. Twelve years previously he removed what was called an ovarian cystoma from the other side of the patient. She afterwards complained of another enlargement. He opened to remove the cyst, and found that when he was dissecting it out from the broad ligament it seemed to extend right down into the vagina. When he separated it as far as he could he found that the uterus had no support, and he removed it along with the cyst.

The President said he had operated on similar tumours, and had the greatest difficulty in enucleating them, as they not only went deeply into the pelvis and vagina, but climbed up under the peritoneum.

The Rotunda Hospital.

The President read the obstetrical and gynaecological reports of the Rotunda Hospital. Their discussion was postponed till next meeting.

UNITED SERVICES MEDICAL SOCIETY.—A clinical meeting of the society was held at the Royal Army Medical College on February 10th, Inspector-General J. PORTER, Medical Director-General Royal Navy, being in the chair. Major C. A. SPENCER, R.A.M.C., showed a man, aged 33, who in July, 1906, suffered from a large hard growth in

the lower part of the abdominal wall attached to the pubes and reaching nearly to the umbilicus. In September, 1906, an attempt to remove the tumour (which was found to be a *Small round-celled sarcoma infiltrating the recti muscles*) failed. Coley's fluid was then given, twelve injections being made into the growth at intervals of two or three days in doses of 1 to 3 minims. A month later, when the general health had much improved, a second series of fifteen injections of 1 to 6 minims was given. Two months later a third series of injections, nineteen in number, was given. Since the end of March, 1907, there had been no further treatment, health had remained perfect, the scar had kept quite firm, and no growth could be found on examination. Lieutenant-Colonel R. J. S. SIMPSON, C.M.G., R.A.M.C., read notes of a case of *Hepatic abscess* in the early stage, treated with 30 grain doses of ipecacuanha given in capsules. The man, an invalid from India, had suffered from enlargement of the liver and suspected abscess since May, 1906. On January 15th, 1909, when the treatment was commenced, a blood count showed whites 15,953, polynuclears 82 per cent. All symptoms rapidly disappeared, the treatment was stopped on January 25th, and on the date of the meeting the patient was perfectly well and had been discharged to duty. Lieutenant-Colonel C. BIRT, R.A.M.C., exhibited two cases of *Incipient tuberculosis* to illustrate the use of the eye and skin reactions. Lieutenant-Colonel Birt also showed the viscera of a man who had succumbed to *General tuberculosis of the lymphatic glands*, together with microscopical preparations and a culture of the tubercle bacillus. An erroneous diagnosis of Hodgkin's disease had been made. There was a mass of glands in the abdomen, weighing 500 grams, and one in the thorax, weighing more than 1 kilog. Tubercle bacilli were present in great abundance, and the lungs and spleen were infiltrated throughout with miliary tubercles. Captain H. B. FAWCOT, R.A.M.C., gave a demonstration on the use of a new medium for the isolation of *Bacillus typhosus* from excreta. Numbers of plates of the medium were shown to illustrate the inhibitory action on the growth of *Bacillus coli* and the distinctive appearances of the colonies of the micro-organisms which grow upon it. Captain J. C. KENNEDY, R.A.M.C., made some remarks on the chart of a case of *Mediterranean fever*.

ASSOCIATION OF REGISTERED MEDICAL WOMEN.—At a meeting on March 2nd, Mrs. STANLEY BOYD in the chair, Miss L. E. SAVILLE, in a paper on the *Medical education of Chinese women*, said that great difficulty was created by their very deficient preliminary education. Of late years there had been some improvement in that respect; the Chinese Government had now appointed an English medical woman on the staff of one of the medical schools for women. Miss IVENS gave the results of an inquiry into the incidence of *Gonorrhoea* in English hospital gynaecological practice among poor but respectable women, chiefly the wives of sailors and dock labourers. Out of 1,052 consecutive out-patients, at least 149 had gonorrhoea in either an acute or chronic form—that is, 14 per cent. of the total number. Of 157 in-patients, 39, or 1 in every 4, had gonorrhoeal lesions demanding operative measures, 30 requiring laparotomy. The speaker believed the extreme frequency of the disease was not fully realized by the mass of the medical profession, and that latent cases were sometimes regarded as simple leucorrhoea, cystitis, or chronic pelvic peritonitis. Life-long ill-health was often produced in women infected by the gonococcus; sterility was associated in 30 per cent. of the cases, and there was always the risk of ophthalmia neonatorum if the patients had children. Exacerbations not infrequently occurred where the disease had been quiescent for many years. Operative treatment was often required for women in poor circumstances who had hard household labour to perform. While fully aware of the difficulties, she believed the interests of a large class of women demanded prophylactic measures of an educational and legislative character.

THE quantity of unsound food surrendered for destruction at riverside wharves under the jurisdiction of the City of London from February 18th to March 6th inclusive amounted to 10 tons 14 cwt. 2 grs.; it consisted chiefly of condensed milk, fruit, and fish.

Reviews.

A NEW EDITION OF AN OLD MANUAL.

OF the making of new books on medical treatment there seems to be no end, and it is an ominous sign that they tend to increase, not only in number, but in bulk. The multiplication of new remedial measures proves the imperfection of those already in vogue. We have now to record the reappearance of an old book on the subject, also in an amplified form. Dr. BURNET YEO's well-known *Manual of Medical Treatment*¹ was first published some fifteen years ago, and its popularity has been fully attested by the call for fresh issues from time to time, up to the present fourth edition.

New light has been thrown upon the nature of many disease processes during the last ten years, and new ideas of treatment have arisen, and although they do not as yet appear to have justified the rejection of older methods, the author has done well to enlist the services of two competent representatives of modern medical thought to aid him in bringing the *Manual* up to recent requirements. The new edition is laid down on much the same lines as its forerunners, and aims at a full description of the rational treatment of disease rather than a condensed summary of actual methods. The rapid strides which surgery has made into the domain of medicine renders it needful to take into close account the conditions under which operative measures constitute the right and proper course to pursue in medical cases. The most recent views, gleaned from trustworthy sources, will be found duly recorded in their appropriate places. The digestive and nervous systems have been the subject of much study in this connexion, and many new ideas, especially those of German writers, are here represented. A general survey of the results obtained by animal extracts, other than thyroid, and of prepared vaccines and serum, is held not to give evidence of more than individual success, more convincing proof being needed to warrant their general adoption.

No pains have been spared to render the book useful to the active practitioner. Lists of prescriptions, of sanatoriums, and of special drugs, with accurate accounts of certain systems of treatment that have come into fashion of late, are ready to his hand to enable him to deal with the disordered action of the human machine. But we miss one aspect of the subject which has of late figured somewhat prominently in new works on therapeutic science. The influence of the mind in the causation of functional organic disorder, although fully recognized, has not been sufficiently utilized in treatment. Old-fashioned gout and new-fangled neuritis are well known to have been cured by removal of mental worry when the most subtle of synthetic drugs has failed to give relief, and it is probable that much functional disorder owns a mental rather than a physical cause. It is not impossible to minister to the mind diseased without throwing physic to the dogs.

THE EXAMINATION OF THE URINE.

WE are glad to welcome a second edition of *Physiology and Pathology of the Urine*,² by Dr. J. DIXON MANN, the first edition of which appeared five years ago. The book has been brought thoroughly up to date, and the same cordial welcome can be extended to it which it was our pleasant duty to accord to the first edition.

During the past five years our knowledge of the physiology and pathology of the urine has considerably advanced, and these advancements are faithfully recorded by the author. As he remarks, "Many substances which formerly were regarded as essentially abnormal are now known to be only relatively so; they are intermediate products of normal metabolism which are rendered abnormal by the inability of the individual who excretes them to utilize them in the ordinary way." Full justice is done to the recent work on the production of acetone, and its appear-

¹ *A Manual of Medical Treatment*. New edition by I. Burnet Yeo, M.D., F.R.C.P., Raymond Craufurd, M.D.Oxon., F.R.C.P., and E. Farquhar Buzzard, M.D.Oxon., F.R.C.P. In two volumes. London: Cassell and Co. 1909. (Cr. 8vo, vol. i, pp. 318; vol. ii, pp. 357. 21s.)

² *Physiology and Pathology of the Urine, with Methods for its Examination*. By J. Dixon Mann, M.D., F.R.C.P.Lond. Second edition. London: Charles Griffin and Co. 1908. (Demy 8vo, pp. 358. 16s. 6d.)

ance in the urine, and considerable additions have been made to the section on glycosuria. Many new and important methods of analysis are described, and, with them, a number of simplified processes by means of which comparative estimates of some of the commoner constituents of urine may readily be made.

The book can be confidently recommended to practitioners and students. It is, in every sense, worthy of the high reputation of its author as a physician and chemist.

DIET AND NUTRITION.

Is a small book on *Human Foods and their Nutritive Value*, Professor HARRY SNYDER, of the University of Minnesota, has contrived to embody a large amount of useful information. He tells us that since 1897 instruction has been given at the University of Minnesota on human foods and their nutritive value, but that no textbook existed which gave in concise form the composition and physical properties of food and discussed the main factors which affect their nutritive value. This book has been prepared to meet that need, but primarily for the author's class room. It is intended for students who have taken a course in general chemistry, but he has endeavoured to present the topics in such a way as to be understood by the average reader. The chapters deal with the general composition of foods and the changes that take place in them during cooking and preparation; the composition of various kinds of foods, such as vegetables, fruits, sugars, legumes and nuts, milk and dairy products, meats and animal foods, cereals and wheat flour. He describes bread and bread making, the purpose and composition of baking powders, the nature of vinegar, spices, and condiments and their action on digestion, the composition and uses of tea, coffee, chocolate, and cocoa. Having thus described the principal articles that form the ordinary diet of civilized man, he discusses their digestibility and nutritive and calorific value, their comparative cost and economical value, and shows how studies in dietetics enable us to construct dietaries which shall be adequate for people under various circumstances, giving the best results at the least cost. He makes no attempt to dogmatize upon the disputed question of the necessary amount of nitrogen, but he quotes with approval a passage taken from Dr. K. Hutcheson's *Food and Principles of Dietetics*:

While one freely admits that health and a large measure of muscular strength may be maintained upon a minimum supply of protein yet I think that a dispassionate survey of mankind will show that races which adopt such a diet are lacking in what for want of a better word one can only describe as energy.

There are useful tables of the nutritive and fuel value and composition of all common articles of food which should be of great assistance to any one desiring to construct a dietary. The book is also well illustrated by microphotographs and other plates. Teachers, moreover, will find a detailed account of laboratory practice and a large number of questions appended relating to each chapter of the book. There are a careful list of references and a good index. We cannot help wondering who constitute the members of such a class as this conducted by Professor Snyder. It would be very useful to medical students, but they get this information, if less concisely, somehow or other in the course of their studies, so we suppose that his class is made up mainly of young women. Nothing could be better as an introduction to a course of cookery than such instruction as that given in these lectures.

The little book on *The Essentials of Dietetics in Health and Disease*,* by Miss POPE and Miss CARPENTER, of New York and Saratoga Springs, is intended to meet the needs of nursing schools and of mothers of families who may wish to learn the scientific principles of dietetics. So far as the latter are concerned, the information given is elementary, yet it is more than those who are quite ignorant of chemistry would be able to follow. Although evidently compiled with care, it is doubtful if the authors possess sufficient knowledge of the subject, as the book contains many mistakes, pos-

sibly attributable to the printer, but which should have been corrected. In the early part of the book are some experiments intended for a class, but ordinary commercial cane-sugar commonly gives a precipitate with Fehling's or Trommer's test; in the experiment described on page 7 the expected point would not be made. On page 9, line 5, "glucose" is apparently written for "sucrose," as cane-sugar is apt to be irritating to the gastric mucous membrane, but glucose is not. On page 11 we are told that no digestion of starch takes place in the stomach—a statement which is of course incorrect, as the greater part of the action of the salivary ptyalin on starch takes place after the bolus of food has reached the stomach. On page 12 only the cellulose of young plants is said to be digested by man, but all kinds of cellulose are indigestible, though the cellulose of old plants is unfit for food. The writer of the first half of the book always spells farinaceous "farinacious," but this solecism disappears from the second part. The hydrochloric acid of the gastric juice is said to be 1 per cent. instead of 1 per mille (p. 22). In giving the causes of indigestion the writer omits the highly important process of mastication, and says nothing about defective teeth and the bolting of food. Cabbages do not cause flatulence because they contain sulphur, but owing to the amount of cellulose they contain, which undergoes fermentation; the sulphur is merely responsible for the production of a certain amount of H₂S, which makes the resulting gas offensive. The statement (p. 89) that various salads are easily digested is of course incorrect. Irish moss is described as an *algae* (*sic*, p. 92), while Iceland moss is said to be used for making bread for diabetics because it contains 80 per cent. of starch! The second part of the book deals in detail with the feeding of infants and children and sick persons; recognized lines are for the most part followed, but it is somewhat surprising to see ice cream and ices given as suitable articles of diet in heart disease. The section on weights and measures, and the table of equivalents, and the chemical symbols seem somewhat out of place in a book of this kind; ammonium is not the name of the gas or rightly described by the formula NH₃; aqua ammonia and aqua calio may be misprints. The last part of the book contains a number of recipes for cooking dishes not especially designed for the use of invalids, and much the same as those to be found in any cookery book; but they seem to be good of their kind.

In something under 400 pages of small octavo Dr. MOIN has tried to express, under the comprehensive title of *Digestion et Nutrition*,† his opinions upon an enormous number of subjects and to touch more or less superficially upon the whole range of internal medicine. He is apparently one of those who pose as superior to the rest of his profession: he indulges in fault-finding of the most varied kind so as to leave upon the reader's mind the impression that Dr. Moïn only is wise, he alone possesses the secret of discriminating what is useful in medical tradition and what is valuable among modern discoveries. He has the pen of a ready writer and the book shows considerable literary skill, but it is not at all a trustworthy guide. It is somewhat difficult to tell whether it is intended for the public or the profession, as, although we should hardly suspect the public of desiring to read a book on this subject, it is much too superficial and too dogmatic to be satisfactory to professional readers. He makes endless statements for the truth of which he affords no kind of evidence—such as, for example, the hereditary nature of gastric ulcer; although Soupault, the only modern author who notices the point, expressly says that "heredity seems to have no influence at all." He also speaks of nutrient enemata as exercising a soothing effect upon the stomach, and therefore directly helping the healing of the ulcer, although the generally received opinion is that the effect of an enema is to give rise to reflex stimulation of the stomach. He uses an immense number of drugs, most of them little known, or relegated to the shops of herbalists, but in other respects he is a follower of the "dosimetric" system. As an example of the style in which he writes we may quote the directions for treatment in cases of entero-colitis:

It is possible to overcome this condition (irritable debility) if one understands how to use *secundum artem belladonna*,‡ *Digestion et Nutrition*. Parle Dr. E. Moïn. *Aperçus de Médecine Pratique*. Paris: Vigot Frères, 1908. (Fcap. 8vo, pp. 376. Fr. 4.)

* *Human Foods and their Nutritive Value*. By Harry Snyder, B.S. London and New York: The Macmillan Company, 1906. (Cp. 8vo, pp. 378. 5s.)

† *The Essentials of Dietetics in Health and Disease*. By A. E. Pope and M. L. Carpenter. New York and London: G. P. Putnam's Sons 1908. (Post 8vo, pp. 253. 5s.)

hyoscyamus, Indian hemp, and Calabar bean. According to circumstances, we should give once or twice a day a pill containing 10 centigrams of extract of hyoscyamus, 3 of Indian hemp, and 5 of powdered Calabar bean; after some days of treatment it will always be found that the vasomotor innervation of the solar plexus seems happily modified.

He sneers at serums and vaccines and the followers of Pasteur thus:

Far better than all the cultivators of microbes and extractors of vaccinal quintessences the practical hygienist knows how to respond truly to all the needs of his patients who will willingly say to the theoretical follower of Pasteur (pastorion theïristant):

Eh! mon ami, tire-moi du danger;
Tu feras, après, ta lavange!

He is equally severe upon German pharmacology, of which he says:

All those gifts of German chemistry (to which should be applied with justice the ancient *timeo Danaos*) are hostile to vitality and become at times important agents in producing post-infectious complications and especially neuroses.

On the other hand, he is a strong advocate for the use of saline purgatives, and says:

It is because our medical era has ignored too much the importance of depurative and eliminative medicine that we now see arterio-sclerosis doing so much mischief.

Yet we should have thought that aperients of all kinds, and especially mineral waters, were never before so largely used. We have, perhaps, devoted an undue amount of space to Dr. Mouin's book, but only quotations are capable of doing justice to its characteristics.

CONSTIPATION.

DR. GUSTAV SINGER, in his article on constipation in Professor Albu's system of treatment,⁶ divides the cases into atonic and spastic forms. A typical instance of each form is described, and this is followed by a very complete discussion of the subject in all its bearings. In the treatment of atonic constipation he deprecates the use of drugs and advocates regimen, recommending regular exercise and a diet composed largely of vegetables and fruit, especially figs and brown bread, with fat in the form of butter, the quantity of meat being small. Some of the worst cases are better treated in a sanatorium. He regards as absurd the attempt to effect intestinal antiseptis by small doses of antiseptic drugs, and points out that Adolf Schmidt found constipated stools to be relatively sterile, and advocated giving agar-agar to aid the growth of bacteria; Dr. Singer cannot say much in favour of this plan, and does not believe that the lactic acid bacillus checks putrefaction, though he admits that it favours the normal functions of the bowel, and that kefir and koumiss act as aperients. He speaks favourably of mechanotherapeutics, and of massage, gymnastics, Swedish drill, and bedroom exercises. Cases of spastic constipation he divides into the symptomatic and primary, the former being the more numerous, as the condition may, he thinks, be set up by many lesions of the other pelvic and abdominal organs as well as by organic disease of the bowel itself, such as ulceration of the colon. He recognizes the fact, to which attention has recently been directed by writers in this JOURNAL, that reflex spasm may cause symptoms so closely simulating ileus as to lead to the abdomen being opened. Chloroform should be employed if necessary to clear up the diagnosis. In practice it is often difficult to draw a sharp distinction between the atonic and spastic forms, which may pass into one another; by the abuse of purgatives atonic constipation may become spastic, while continued enemata may cause spasm of the rectum. For the treatment of the spastic form he recommends sedative remedies, especially rest and warmth, physical and mechanical means being here out of place. The most useful drug, he thinks, is belladonna; he also recommends eumydrine (methyl-atropine nitrate) and an enema of warm oil (5 to 8 oz.) injected slowly and retained all night, the bowel being washed out in the morning with warm camomile tea. In some cases of spasm of the rectum he recommends dilatation with bougies or with a distensible elastic bag. The diet recommended is chiefly vegetable but soft and

free from cellulose. There is no mention of the use of bismuth meals and x rays in the diagnosis of the forms of constipation, which are somewhat serious omissions in a publication dated 1909.

The scope of Dr. GANT's work on *Constipation and Intestinal Obstruction*⁷ can best be indicated by the following quotation from his preface:

During the past fifteen years such flattering success has been mine with the non-medical and surgical treatment of these affections that I have thought it worth while to emphasize in this work the drugless management of constipation and obstruction. From what I have been able to find in the literature and from my conversations with medical men, in addition to my derived from psychotherapy, diet and physical measures such as bodily movements, massage, mechanical vibration, and electricity, have not received the marked attention they deserve by physicians in general when outlining a plan of treatment for the relief and cure of the different types of costiveness.

The greater part of the book is taken up with a description of the various causes of intestinal obstruction, apart from what is generally called constipation, and the surgical measures required for their treatment. Chapters XVII and XVIII deal with the treatment of ordinary constipation by diet and exercise, while Chapters XXVI and XXVII are devoted to a description of treatment by drugs and enemata. The author is apparently of opinion that constipation is much more common in America than on the continent of Europe and places America in this respect only second to England; he attributes this prevalence mainly to the abuse of purgatives, and he thinks the unrestricted sale of these is largely responsible for their abuse. Yet in France and Germany the sale of aperient medicines is practically unrestricted, and certain forms of them are widely advertised, so that if the habit of taking purgatives does not obtain to the same extent, it cannot be explained by the difficulty of procuring them. We are disposed to think that the author, like some surgical specialists on this side of the Atlantic, exaggerates the frequency of serious cases, and we believe that in England there are few which do not yield to treatment by far simpler means than those which he mainly favours; we notice, indeed, that he admits the success obtained in America by Christian Scientists in the treatment of these cases!

A DOCTRINAL RENAISSANCE.

The activity of the Montpellier School of Medicine has been manifested of late years by many important contributions to medical literature, and we have now to record the appearance of a very large work on the subject of the Diseases of the Respiratory Apparatus, from the pen of Dr. GERMAIN REY of Toulouse.⁸ His treatise is founded upon the medical doctrines of the Montpellier School, and it is ushered in by a veritable psalm to the glory of that seat of learning, in the course of which it is claimed that its professors have inaugurated a magnificent doctrinal renaissance by their recognition of the importance of the vital element in all morbid processes. It is maintained that the new light thrown upon the part played by the blood and its serum by Wright and others must reassert the position of the *vis medicatrix Naturae*, and restore to a great extent the views of our forefathers in medicine.

To what extent this renaissance of doctrine is due to the Montpellier School is not clearly manifest, but it may be defined as implying a fuller recognition of vital force resident in all living matter—for example, the force whose presence in the fertilized egg leads to the development of the chick, while its absence from the non-fertilized egg under precisely similar surroundings is followed by decomposition. Applied to the study of disease, the doctrine defines it as a lesion of vital force manifested by the evolution of abnormal action, sometimes detrimental and sometimes useful, resulting in a conflict between the vital unit and some outside cause which disturbs functional harmony. In most cases the disease of an organ so-called

⁶ Heft 6. Die Atonische und die Spastische Obstitution. Von Privatdozent Dr. Gustav Singer. Halle & S.; C. Marhold. 1909. (Med. 8vo, pp. 46. M.1.)

⁷ *Constipation and Intestinal Obstruction (Obstitution)*. By Samuel Goodwin Gant, M.D., LL.D. 250 original illustrations. Philadelphia and London: W. B. Saunders and Co. 1909.

⁸ *Traité Méthodique et Clinique des Maladies de l'Appareil Respiratoire*. Based on the Medical Doctrines of the School of Montpellier. By Germain Rey, of Toulouse. Montpellier: Coulet et Fils. 1909. (Roy. 8vo, pp. 912. Fr. 15.)

is only the local manifestation of a general condition, and it becomes the business of the physician to study the morbid state as a whole, and this can only be done satisfactorily by means of systematic analysis.

Dr. Rey's book is too large to admit of detailed examination, and it must suffice to record that every morbid condition of the respiratory apparatus, exclusive of the upper respiratory passages, which have now apparently passed out of the field of the physician into that of the specialist, is closely examined, discussed, and defined in accordance with the methods advocated by the author and his school.

The keynote of the method is analysis, not only of symptoms, but also of the various indications for treatment. The order of subject is that usually employed in textbooks, but every point in pathology, etiology, diagnosis, etc., is followed out with far greater minuteness than is customary, and although many of the assertions are somewhat dogmatic, a reasoned argument in their favour is always at hand to explain the train of thought which has led up to them. The psychic element in disease is closely regarded, and, although the value of modern research is fully recognized, it is obvious that the older clinical methods are held in high esteem as shown by the numerous references to the works of a date anterior to 1890. Although unable to rise to the point of enthusiasm attained by the author for his "doctrinal renaissance," we can cordially commend his work to the notice of those who are engaged in the clinical teaching of beginners in medicine. The acquirement of such a habit of clinical analysis as is here exemplified, cannot fail to be a precious possession to the clinician in after-life and at the present time, when theories succeed one another with breathless rapidity, it is of vital importance that they should be subjected to this test of clinical examination before they are allowed a prominent place among the accepted doctrines of the profession.

HYPNOTISM AND BUNKUM.

THE author of *Hypnotic Therapeutics in Theory and Practice*,⁹ whose name is QUACKENBOS, tells us that he has been engaged in the study of hypnotism for a quarter of a century, and the philosophy and material contained in the present work is based, he states, on "seven thousand separate experiences with the subpersonal minds of intellectual men and women." The book is typical of a large number of others coming from America, the land of Christian Science, Mentalcure, New Thought, and any number of others of the fantastic progeny of a disorderly imagination. The author writes with a genuine though perverid enthusiasm, and makes great use of strange, mystical, and high-sounding terms like "ethico-spiritual force," "psychics," "metapsychics," "pneumatic," and so on. "Pneumatic" perhaps furnishes the most apt description of the book, though perhaps not in the sense in which the author uses the term. For the author hypnotism is "the therapeutics of the transliminal," in which we are "capable of acting independently of a visible corporeity, . . . possess supernatural knowledge and wield ultra-normal power, and are gifted with a measure of prescience that on occasion forecasts what is to be." In the "transliminal" (which evidently does not correspond to the "subconscious" as usually employed) we can enter into communication, by the action of mind on mind, with other transliminal selves, human or "extra-human." Hypnotism is merely one means of reaching and modifying the transliminal self, which transliminal self is not only all-powerful but all-good. It is therefore impossible to suggest evil to an all-good transliminal self or to do harm by hypnotic means. Hypnotism, therefore, is always right, telepathy—which "no educated person will deny"—is right, veridical or "co-cognitive" dreams are right, and all is right as right can be—that is, so far as transliminal hypnotism is concerned. Dr. Quackenbos, however, disapproves of all other exploiters of the occult, and puts under the ban the Mind Curists, Viticulturists, Esoteric Vibrationalists, Christian Scientists, Venopaths, and so on—in fact, "the whole spawn of charlatans, impostors, faith-healers, seers, and other dabblers in hypnotism," who, he maintains, "ought to be buried out of sight in the bottomless bogs of their own ignorance and knavery."

⁹ *Hypnotic Therapeutics in Theory and Practice*. By John Duncan Quackenbos, A.M., M.D. London and New York: Harper and Brothers, 1908 (Demy 8vo, pp. 312, 7s. 6d.)

The author of a recently-published book on *Suggestive Therapeutics*,¹⁰ Dr. HENRY S. MUNRO, says in his preface that it is not intended principally or even mainly for the neurologist and psycho-therapist, but rather "to instill (sic) into the vast mass of the profession to whom this entire field is as yet *terra incognita*, those basic principles of physiological psychology upon which the scientific therapeutic application of suggestion in all its forms necessarily depends." A careful perusal of the book, however, fails to reveal any description or analysis of the "basic principles of physiological psychology," but instead we have an account of the method of inducing hypnosis employed by the author—who appears to have gone about from city to city giving demonstrations to medical men—with occasional and not always accurate references to elementary physiology and cerebral anatomy; a great deal of talk about the "subconscious mind," the "true ego," the "ideal man," "psychic influence," and so on, and statements with regard to numbers of cases of ill-described illnesses which had recovered under the author's hands. It is exceedingly difficult to follow the author in his meanderings, partly because of the lack of any sustained argument or methodical discussion and partly because of an extraordinary fashion of having a few words—apparently chosen at random—printed in large block type on almost every other line.

Another book recently issued on this subject is *The Marvels of Hypnotism*,¹¹ by Dr. GERAUD BONNET of Oran and Sidi-bel-Abbès in Algeria, whose *Traité Pratique d'Hypnotisme et de Suggestion Thérapeutiques* we reviewed not long ago. The last-named work was the first, and the present book is the third, of a series by Dr. Bonnet. A second book on the transmission of thought we have not received, and know nothing of it beyond its suggestive title; but whereas the first work was entirely practical in character the last book is largely theoretical, and, in so far as it gives an account of hypnotic phenomena, is an attempt to justify its title. Its author, who regards such things as telepathy and Blondlot's *n* rays as facts beyond dispute, believes also in "nervous force," the exteriorization of this nervous force—producing, for example, movements in inanimate objects—and action at a distance. He relates numerous observations of his own and experiments made by others in support of his conception of hypnotism. Notwithstanding this dubious mixture of mysticism and science, Dr. Bonnet's book is interesting, and contains a good deal of information of practical use, particularly as to the place of suggestion in medical practice, a matter treated with a moderation not always encountered in books of this kind.

PHOTOGRAPHIC OPTICS.

DR. G. LINDSAY JOHNSON'S *Photographic Optics*¹² is a textbook intended primarily for the professional optician, but is written at the same time for the guidance of those wishing to understand the scientific principles underlying the main facts of photography. In his preface Dr. Johnson has disarmed criticism by pleading guilty to the "poverty of explanation" in the work owing to the mass of theoretical and practical detail inevitably included, but it is to be feared that the resulting obscurity will prevent the book becoming popular with the elementary student. To those, however, who come to a study of optics with a thorough knowledge of elementary geometry, a slight acquaintance with the rudiments of trigonometry, and with the theoretical knowledge of light required at such an examination as the Preliminary Scientific of the London University, the book will prove an invaluable guide. It is thoroughly up to date, and includes an account of the principles of even so late a development of moving colour photography and projection as that accomplished by Mr. G. A. Smith, and shown a month or two ago at the Society of Arts. Considerable attention

¹¹ *Les Merveilles de l'Hypnotisme, Considérations Théoriques et Applications Diverses*. By Dr. Geraud Bonnet. Paris: Jules Roussel, 1909. (Post 8vo, pp. 281, F. 3.50.)

¹² *Photographic Optics and Colour Photography, including the Camera, Kinetograph, Optical Lantern, and the Theory and Practice of Image Formation*. By George Lindsay Johnson, M.A., M.D., B.S., F.R.C.S., etc. London: Ward and Co., 1909. (Demy 8vo, pp. 314, 14 plates, 5 in colours, and 170 illustrations. 7s. 6d.)

has been paid to the theoretical side of the subject, and detailed explanations are given of just those difficulties which suggest themselves to the optician, and in a lesser degree to the photographer in the beginning of their careers. While, as has been said, parts of the book will inevitably prove obscure to those who come to it without the necessary preliminary training, it contains a quantity of material of very great interest even to the amateur. The special chapter devoted to colour photography provides an excellent instance of how a highly technical subject can be treated adequately in popular language. The most technical parts of the work are relieved with occasional flashes of humour. Thus, after several pages dealing with speed indicators, the author suggests that a policeman wishing to trap a motorist should carry a tuning-fork, vibrating forty-two times a second, and look past one of the vibrating prongs at the spokes of the wheel as the car goes by. The wheels would appear stationary if driven at the statutory speed. Other tuning-forks vibrating at slightly higher rates would decide the actual speed with accuracy; but, as the author remarks, "while any exceeding of the speed limit can be determined, it is highly improbable that it would be received as evidence in court." There are a considerable number of misprints, but the majority have been detected, and Messrs. Ward have printed a table of errata for those who have already purchased the volume.

ANTISEPTIC OR ASEPTIC.

M. LUCAS-CHAMPIONNIÈRE has published in a handy octavo volume¹⁸ a collection of lectures delivered at the Hôtel-Dieu.

The book is an important and valuable contribution to the literature of antiseptic surgery by one of its earliest apostles. Forty years ago he studied the subject under Lister, and was one of the first surgeons to adopt it and to introduce it in Paris, with the success which is well known throughout the surgical world. Many valuable lessons are to be learnt from the perusal of M. Lucas-Championnière's book, which may be recommended to the attention of the younger generation of surgeons who have been brought up in the aseptic school. Some of them have not yet fully realized the dangers of the absence of antiseptics in ordinary everyday surgical practice. In discussing the relative value of antiseptic as contrasted with aseptic surgery interesting statistics are given showing the certainty with which operations in what is perhaps the most dangerous branch of surgery—the surgery of the joints—has been carried out without a single case of death from septicaemia during a period of over thirty years. M. Lucas-Championnière has probably operated by suture for fracture of the patella on more occasions than any living surgeon; 1,135 cases of radical cure of hernia, without a single death attributable to septic infection, are also recorded, and the author states that he has never employed gloves or masks, as now used by many aseptic surgeons. M. Lucas-Championnière's experience in antiseptic surgery dates back to November 20th, 1874, when he performed the first operation under the antiseptic system in France, and probably one of the first in the world outside the British Isles.

The expressions of opinion contained in this book are founded upon temperate argument and sound judgement, whilst at the same time there is evident the fervent enthusiasm of a disciple who learnt the gospel from the lips and from the acts of the great master himself, and is wholly imbued with the invaluable blessings conferred by him on suffering humanity.

An excellent portrait of Lord Lister forms a frontispiece to the volume.

NOTES ON BOOKS.

THE *Medical Register* for 1909¹⁴ was issued on March 15th; it contains 40,257 names, as compared with 39,827 names last year, 37,878 names in 1903, and 35,836 in 1899. A part of the increase, not a very large part, is due to the growth of the Colonial list, which now contains the names of 219 Colonial graduates, of whom 79 register an address in this country. The foreign list contains 27 names; in

every case the degree registered is from an Italian university, and of this total 12 practise in Great Britain, all of them in London, and 6 in British colonies or dependencies. It appears that altogether 781 names were removed from the *Register* during 1908—572 on evidence of death, 3 under penal provisions, 3 on ceasing to practise, and 103 under Section XIV of the Medical Act, 1858, which empowers the Registrar to remove a name if no answer is received to a letter of inquiry. The *Dentists Register*,¹⁵ received on the same date, contains 4,994 names; 2 are those of Colonial and 22 of foreign dentists. The percentage of registered United Kingdom dentists who are now licentiates or graduates in dentistry is 58.29, and of the licentiates and graduates in dentistry 351 have registered surgical or medical qualifications in addition to a dental qualification.

The edition of the *Medical Annual*¹⁶ for 1909 is in external appearance identical with its predecessors of the last few years, but on turning over its pages seems more freely illustrated. There are, for instance, in the present or twenty-seventh edition, as many as 54 coloured plates, as well as some 160 engravings. Of the coloured plates a large number appear in connexion with articles on diseases of the eye, of which some are written by Mr. ERNEST MADDOX and others by Mr. J. H. YEARSLEY. The book as a whole is the work of some thirty-seven contributors, English, American, and Continental; with few exceptions they are men well known as authorities or writers on the subjects with which they deal. In connexion with many previous editions of this book we have drawn attention to its value, especially to those engaged in active practice: they will often obtain from it a hint as to the treatment of a puzzling case, and even if constant students of current literature they cannot fail to find utility in its summaries of papers which have appeared in various periodicals on special points in medicine and surgery and in the field of diseases covered by the various specialities. The latter, indeed, receive a generous amount of notice throughout the work. In addition, the volume contains abstracts of the more important legal decisions affecting medical men and the public health delivered during the preceding twelve months, and a very useful classified list of the principal medical works published during the corresponding period. There is a good general index, but reference to its contents would be facilitated if a list were given of the headings of each separate article.

The edition for 1907 of *Die therapeutischen Leistungen*, edited by POLLATSCHER and NADOR,¹⁷ was received on March 15th. It is a yearbook intended for the use of practitioners, and contains abstracts, under alphabetical headings, of papers published during 1907 deemed by the authors to be of more or less permanent importance. It is intended, of course, as a work of reference, and the editors have taken pains to provide an excellent system of indices, an alphabetical list of diseases, another of authors, general subject index, and, finally, a short index of drugs and other remedies.

The volume designated *The World I Live in*¹⁸ is by Miss H. KELLER, the talented American whose marvellous progress and proficiency in a literary education, in spite of being the subject both of blindness and deafness from infancy, were set forth in a previous autobiographical work (*The Story of My Life*, reviewed in the BRITISH MEDICAL JOURNAL of November 28th, 1903, p. 1409). The chapters of her new book are full of psychological as well as of physiological interest. Those familiar with the methods of education of the blind will perhaps be prepared for the statements made under the heading of "The Seeling Hand," but those comprised under such titles as "The Hands of Others" and "The Hand of the Race," evidence mental discrimination on the part of the perceiver of no common order. In fact, Miss Keller seems to be an expert "thought-reader," and is able to judge of the character, moods, and even tricks of speech of those with whom she is brought into contact. "Mark Twain's hand," she says, "is full of whimsies and the drollest humours, and while you hold it the drollery changes to sympathy and championship." Of the hands of our own profession she writes in complimentary terms, stating that "if the physician is a man of great nature,

there will be healing for the spirit in his touch. This magic touch of well-being was in the hand of a dear friend of mine who was our doctor in sickness and in health. His happy, cordial spirit did his patients good whether they needed medicine or not." The book is illustrated by four admirable photographs, one of which represents Miss Keller "listening" to the trees and enjoying the rustle of the leaves through the medium of fine vibrations conveyed along the trunks! Of the sense of smell she says "there is something of the fallen angel about it," though she proceeds to tell us that in her own experience she learns and remembers much from olfactory impressions. No less than three chapters are devoted to the subject of dreams, and these we may briefly epitomize in her own sentence: "My dreams do not seem to differ very much from the dreams of other people." Of the book we have said enough to show that it is a remarkable work by a remarkable author.

Dr. F. F. STRONG of Boston, in his book entitled *High-Frequency Currents*,¹⁸ comes forward not so much with an impartial survey of the whole subject as with an explanation and defence of his own methods as an American electro-therapist. He claims to rank as a pioneer of high-frequency therapeutics on the ground that since 1896 he has been employing the bipolar high-potential currents of Tesla, which, he says, possess considerable advantages over the better-known low-potential currents of d'Arsonval and the monopolar high-potential effects of Oudin. Dr. Strong's theory to account for the immunity of the human body is that high-frequency currents are simply forms of vibration, like sound waves, and their passage involves the transmission of energy and not of matter. He has treated pulmonary tuberculosis by high-frequency. The writing would have benefited by further revision, and there are some misspellings, of which "J. J. Thompson" is an example.

It has not hitherto been easy for individuals who wished to possess a general knowledge of man's structure, nature, history, and relationships, to gain that knowledge, except at the expense of considerable labour and extensive reading, for the data, though numerous, are scattered, and they are often given in extremely technical language. LUDWIG HOPF'S *Human Species*¹⁹ is an attempt to provide the general knowledge so many people require in compact form and in simple language. Commencing with a few general considerations, the author passes on to the distribution of man in space and time. Then in a very general manner he deals with the anatomy of the various systems and organs, which he compares with those of other animals. In a similar manner he deals with the physiology of the senses, with psychology, and social life, art and handicrafts and music; he brings his volume to a conclusion with a consideration of pathology and diseases as they affect man and his more immediate neighbours. The book will appeal to those who like to possess a superficial knowledge of many things, and it will probably induce some of its readers to dip deeper into many of the fascinating subjects upon which it touches.

¹⁸ *High-Frequency Currents*. By Frederick Finch Strong, M.D. London: Reisman, Limited. 1909. (Royal 8vo, pp. 309; 183 illustrations. 2s. 6d.)

¹⁹ *The Human Species*. By Ludwig Hopf. London: Longmans, Green and Co. 1909. (Med. 8vo, 477 pp., 216 figs. 10s. 6d.)

MEDICAL AND SURGICAL APPLIANCES.

The Rotary Haemoglobinometer.

DR. ARTHUR J. HALL (Lecturer on Practical Medicine, Sheffield University) writes: The value of a quantitative estimation of haemoglobin, either alone or as part of a complete blood examination, is generally recognized. So far, however, it is not made use of by the majority of practitioners in this country to the extent that it might and ought to be. One cause of this is, undoubtedly, the length of time involved in making such estimations. Any method which, while reasonably accurate and reliable, reduces the time and simplifies the apparatus required, is likely to increase its use in general practice. No method could be devised which would exceed in simplicity of apparatus and rapidity of performance that suggested by Tallqvist in the well-known form of the "haemoglobin scale" books. But, like other methods, it has its defects, and, according to some who have tried it, those defects render it unreliable. It is with the view of diminishing or removing some of the sources of error, in a method which presents so many clinical advantages to the general practitioner, that I bring forward the rotary haemoglobinometer

It is founded on the same principle as the haemoglobin scale of Tallqvist—namely, the saturation of a piece of absorbent paper with pure blood, and its comparison with a set of artificial standard tints representing normal blood and its dilutions.

Description.—The apparatus consists of a rotating metal disc, on the front surface of which the standard colour tints are arranged at intervals near the circumference, whilst the percentage numbers corresponding to each tint are similarly arranged on its posterior surface. The disc is encased between two rectangular plates of ebonite (size 2½ in. by 2½ in.), each of which has a small round hole (C in front plate) in it corresponding with that part of the circumference of the revolving disc upon which the colour tints and percentage numbers are respectively situated. When the disc is rotated by the forefinger (A) the successive standard tints in turn completely fill the hole in

the front plate, whilst on turning the instrument over, the corresponding percentage of haemoglobin which that tint represents, can be read off through the hole in the posterior ebonite plate. The accompanying illustration shows the general arrangement as seen from the front. Close beside the hole, C, there is a second hole in the front plate of the same size and shape (C'). By means of a narrow space between the two plates (D and D') a slip of absorbent paper can be pushed in, as at D', so as completely to occupy the hole (C').

Method of Use.—After pricking the finger or ear of the patient whose blood is to be examined, a slip of absorbent paper is torn out from one of the small books of slips provided with the instrument, and a good-sized drop of blood is carefully blotted up at one end so as to make a stain larger than the size of the opening at C'. The slip is then pushed into the slot D', so that the blood stain fills up the hole C'. The disc is then revolved by its projecting milled edge at A' until the tint is found with which it most nearly corresponds. The instrument is then turned over, and the haemoglobin percentage read off through the hole in the under surface.

The instrument can only be used in ordinary daylight.

Advantages.—The advantages which this instrument offer for the busy practitioner are:

1. Its small bulk.
2. The absence of all glass apparatus or liquids.
3. The ease with which the colours can be compared owing to:
 - (a) The exactly similar size and shape of the two areas of colour to be compared.
 - (b) The absence of any other colour from the visual field whilst making the estimation. This is obtained by having the upper ebonite plate of a uniform dull black.
 - (c) The absence of any knowledge as to the actual percentage of the various tints until after the comparison has been made.

This last advantage is a real one, for, as has been pointed out by Sahli, the unconscious influence which a knowledge of the percentages may have upon the examiner at the time of comparing the colours is not inconsiderable. Sahli has to a certain extent met this difficulty in his modification of the Gowers haemoglobinometer, but by means of the rotary haemoglobinometer, on account of the various tints being arranged in a circle, this particular object can be more completely attained than by instruments of other shapes. If an estimation has been made, and the percentage of any particular tint ascertained, it is only necessary to rotate the disc again out of sight, to be able to repeat the examination without in the least knowing the position of the scale.

The instrument has been made at my suggestion by Mr. T. Hawksley, 357, Oxford Street, London, to whom I am greatly indebted for the great pains he has taken in preparing an original standard set of colours, which seem very satisfactory, and for the neat and compact instrument which he has evolved from my crude suggestions. The whole case containing needles, rotary haemoglobinometer, and books of slips can be easily carried in the pocket.

THE COMPOSITION OF SOME PROPRIETARY DIETETIC PREPARATIONS.

I.

THE importance of the part played by diet in promoting health or causing disease has perhaps never been so widely recognized as at present; and although a vast field remains for researches into the intimate nature of foodstuffs and the exact changes they undergo in metabolism, a point has already been reached far beyond the empirical rules which governed medical regulation of diet at an earlier day. The process of preparing animal and vegetable materials for use as foods has been developed until the original materials are frequently no longer recognizable, and artificial foods are manufactured of heterogeneous materials in such a way as to secure the desired balance between the different constituents, either to furnish all the elements of a complete diet, or to produce a food suitable for use in various forms of illness.

As unfortunately too often happens, however, advancing knowledge has been applied not only to effect real improvements, but also sometimes for the skilful simulation of improvements, so that it is of great importance to be able to discriminate among the large numbers of dietetic articles either manufactured or modified in their properties for a particular purpose, and to distinguish those which possess real merit from those which do not, or for which a price is charged which is out of proportion to their merits.

With a view to assisting in the formation of correct judgements in this matter, it is proposed to publish in the BRITISH MEDICAL JOURNAL the results of careful analysis of a number of dietetic preparations.

I.—MEAT WINES.

Results of the examination of certain meat wines will first be given. There are several much recommended by the makers as tonics, to be taken during convalescence and in conditions of debility, and there can be doubt that very considerable quantities of wines are consumed in this way. In order that the use of or abstinence from such a wine may be advised, the medical practitioner requires to have some knowledge of its alcoholic strength and of the proportion of meat extract or other meat preparation contained in it; in some cases other constituents, such as iron, malt extract, cinchona preparations, etc., are stated to be present, and the dosage of these also should be known; information as to the general nature of the wine is, of course, also useful. In the following paragraphs the results of calculation from the percentage composition are given, showing how much of each of the principal constituents is contained in a wineglassful of the wines in question; "a wineglassful" is taken to be 2 fl. oz., which is the measure conventionally recognized as its equivalent, although the actual size of wineglasses varies very greatly.

To facilitate comparison, the following short table of the average alcoholic strength of ordinary wines, with the amount of pure alcohol in a wineglassful of each, is given:

Wine.	Percentage of Alcohol by Volume.	Amount of Pure Alcohol in a Wineglass.
Port	20	3½ fluid drachms.
Sherry	20	3½ "
Champagne	10 to 15	1½ to 2 "
Hock	10	1½ "
Claret	9	1½ "

It is not possible, without a complex analysis of a very large quantity, to determine positively whether meat extract only, or some other meat preparation, is contained in a wine. In some instances the makers state that meat extract is added, while in others the same addition is implied; in other cases, again, such terms as "beef essence," "beef jelly," and "pure meatnourishment (not extractives)"

are used. The total nitrogen found has accordingly been calculated into its equivalent of meat extract, assuming the latter to contain 8.9 per cent. of nitrogen, which is the percentage found by analysis in a well-known brand of high-class meat extract. This introduces a small error in favour of the wine; natural wine contains a small proportion of nitrogen, which may be from 0.01 to 0.1 part per 100 fluid parts; as it is impossible to say how much was contained originally in the wine used in a given case, no correction has been made for this, but the whole of the nitrogen has been treated as derived from meat extract; this should, therefore, be borne in mind in judging of the results given. The acidity of the wines is expressed in the usual way, the fixed acid being calculated as tartaric, and the volatile acid, or that portion which is lost on boiling down the wine, as acetic acid.

BOVRIL WINE.

This is prepared by Bovril, Ltd., London, E.C. No price is marked on the bottle; the usual retail price appears to be about 1s. 3d. The bottle held 9½ fluid ounces.

It is described on the label as

A nutritive tonic containing the properties of "Bovril," Extract of Malt, and Selected Port Wine.

Directions.—"Half a wineglassful may be taken three times daily."

Analysis gave the following results:

Alcohol	20.15 per cent. by measure.
Total solids	13.2 parts per 100 fluid parts.
Meat extract (calculated from nitrogen)	0.5 " "
Fixed acidity	0.34 " "
Volatile acidity	0.10 " "
Reducing sugar calculated as glucose	10.2 " "
Ash	0.5 " "

Glucose was identified by appropriate tests; a part of the sugar present may have been maltose, and if this were added as malt extract, as implied by the label, it would be accompanied by the nitrogenous constituents of the extract, and the whole of the nitrogen should then not be attributed to meat extract. According to this formula, a wineglassful would contain:

Pure alcohol	3½ fluid drachms.
Meat extract	4.4 grains.
Glucose	88.0 "

"LEMCO" WINE. LIEBIG'S EXTRACT OF MEAT AND MALT WINE.

This wine, prepared by Stephen Smith and Co., Ltd., Bow, London, E., is sold at the price of 1s. 9d. a bottle, containing 13½ fluid ounces.

Directions.—"A wine-glass full three times a day, children half the quantity."

Analysis gave the following results:

Alcohol	17.26 per cent. by measure.
Total solids	15.7 parts per 100 fluid parts.
Meat extract (calculated from nitrogen)	0.6 " "
Fixed acidity	0.31 " "
Volatile acidity	0.12 " "
Reducing sugar calculated as glucose	12.8 " "
Salicylic acid	trace. " "
Ash	0.4 " "

Glucose was identified by appropriate tests. According to this formula, a wineglassful would contain—

Pure alcohol	2½ fluid drachms.
Meat extract	5.2 grains.
Glucose	112.0 "

COLEMAN'S WINCARNIS.

This wine, prepared by Coleman and Co., Limited, Wincarnis Works, Norwich, is sold in bottles, containing 12½ fl. oz., and costing 2s. 9d.

Directions.—"A small wineglassful may be taken three times a day."

It is described on the label as

Made from Choice Wine, Liebig's Extract of Meat, and Extract of Malt.

Analysis gave the following results:

Alcohol	19.6	per cent. by measure.
Total solids	22.9	parts in 100 fluid parts.
Meat extract (calculated from nitrogen)	1.2	" "
Fixed acidity	0.26	" "
Volatile acidity	0.09	" "
Reducing sugar calculated as glucose	18.2	" "
Ash	0.4	" "

Glucose was identified by appropriate tests; a part of the sugar may have been maltose, and if this were added as malt extract, as stated on the label, it would be accompanied by the nitrogenous constituents of the extract, and the whole of the nitrogen should not then be attributed to meat extract.

A second bottle which was examined contained only 18.1 parts of total solids in 100 fluid parts.

According to the above formula, a wineglassful would contain:

Pure alcohol	3 fluid drachms and 8 minims
Meat extract	10.5 grains
Glucose	159 "

GLENDENNING'S BEEF AND MALT WINE.

This is prepared by W. Glendenning and Sons, Limited, Newcastle-on-Tyne, and is sold at 2s. a bottle, containing 12 fl. oz.

Directions.—"A wineglassful may be taken twice a day with food or after."

It is described on the label as

Made from Alto Douro Port, Beef Jelly, and Malt Extract.

Analysis gave the following results:

Alcohol	20.8	per cent. by measure.
Total solids	13.5	parts in 100 fluid parts.
Meat extract (calculated from nitrogen)	0.4	" "
Fixed acidity	0.31	" "
Volatile acidity	0.09	" "
Reducing sugar calculated as glucose	10.6	" "
Ash	0.3	" "

Glucose was identified by appropriate tests; a part of the sugar may have been maltose, and if this were added as malt extract, as stated on the label, it would be accompanied by the nitrogenous constituents of the extract, and the whole of the nitrogen should not then be attributed to meat extract. According to the above formula, a wineglassful would contain:

Pure alcohol	3½ fluid drachms.
Meat extract	3.5 grains.
Glucose	95 "

BENDLE'S MEAT-PORT NUTRIENT.

Two kinds of wine are supplied under this name by Sutton Bendle and Co., 148, Sloane Street, London, S.W. They are distinguished by a white and red capsule respectively, the latter being stated to contain twice as much "meat substance" as the former. The white capsule variety was taken for examination: no price is stated on the label, but the usual retail price appears to be about 3s. per bottle, containing 13½ fl. oz.

Directions.—"A wineglassful from three to six times a day."

This is described on the label as follows:—

A really genuine nutritive meat wine. Guaranteed to be made with the finest old tawny port (not tarragons), and to contain pure meat nourishment (not extractives) equivalent to seven per cent.

Analysis gave the following results:

Alcohol	20.3	per cent. by measure.
Total solids	10.9	parts in 100 fluid parts.
Meat extract (calculated from nitrogen)	2.5	" "
Fixed acidity	0.19	" "
Volatile acidity	0.03	" "
Reducing sugar calculated as glucose	8.0	" "
Ash	0.5	" "

Glucose was identified by appropriate tests, and no evidence was obtained of the presence of any other sugar.

According to the above formula, a wineglassful would contain:

Pure alcohol	3½ fluid drachms.
Meat extract	22 grains.
Glucose	70 "

"BIVO." BURROUGHS, WELLCOME AND CO.'S BEEF AND IRON WINE.

This is prepared by Burroughs, Wellcome and Co., Snow Hill, E.C. No price is marked on the bottle or package or the contained circular, but the usual retail price is about 2s.; the bottle contained 8½ fl. oz.

Directions.—"One tablespoonful or more, plain or diluted with water, thrice daily for adults, or as ordered by the physician."

Analysis showed the wine to contain 19.2 per cent., by measure, of alcohol. A small proportion of the nitrogen present was found to be liberated as ammonia on treating with alkali, and this was therefore determined and deducted from the total nitrogen, only the remainder being calculated as meat extract. The results obtained were as follows:

Alcohol	19.2	per cent. by measure.
Total solids	17.7	parts per 100 fluid parts.
Meat extract (calculated from nitrogen)	3.4	" "
Fixed acidity	0.75	" "
Volatile acidity	0.06	" "
Iron	0.23	" "
Reducing sugar calculated as glucose	11.5	" "
Salicylic acid	trace.	" "
Ash	1.2	" "

Glucose was identified by appropriate tests, and no evidence was obtained of the presence of any other sugar. According to this formula, a wineglassful would contain:

Pure alcohol	3 fluid drachms
Iron	2.0 grains
Meat extract	30.0 "
Glucose	100.0 "

"VIN REGNO." PEARSON'S LIEBIG'S BEEF WINE.

This is prepared by Liebig's Wine Co., Liverpool and London, and is sold at the price of 2s. 9d. a bottle, containing 13½ fl. oz.

Directions.—"Take a wineglassful three times a day and keep in a cool place."

On the label appear the words:

Chief Ingredients, Choice Port Wine, Essence of Beef, Malt Extract, and Quinine.

Analysis gave the following results:

Alcohol	16.05	per cent. by measure.
Total solids	13.45	parts per 100 fluid parts.
Meat extract (calculated from nitrogen)	0.3	" "
Fixed acidity	0.36	" "
Volatile acidity	0.12	" "
Reducing sugar calculated as glucose	7.4	" "
Ash	0.3	" "
Alkaloid	slight trace.	" "

Glucose was identified by appropriate tests; a part of the sugar present may have been maltose, and if this were added as malt extract, as stated on the label, it would be accompanied by the nitrogenous constituents of the extract, and the whole of the nitrogen should then not be attributed to meat extract.

Only a slight trace of alkaloid was present. The quantity extracted from nearly half a pint of the wine was too small to be weighed or identified, and did not show even such a delicate test for quinine as the formation of a fluorescent solution. The wine had no bitter taste. According to the above formula, a wineglassful would contain:

Pure alcohol	2½ fluid drachms.
Meat extract	2.6 grains.
Glucose	65.0 "

SUMMARY.

Speaking generally, it will be seen that all the meat wines examined are stronger in alcohol than claret or hock, and approach the strength of sherry or port. With regard to the amount of meat extract contained, an ordinary good teaspoonful of extract of meat—such as would be used for a breakfastcupful of bouillon—weighs about 130 to 140 grains. The quantities of such a bouillon represented by one wineglassful of the wines described above would therefore vary from about 4 tablespoonfuls down to about 1½ teaspoonfuls.

The percentages of alcohol, sugar, and meat extract, and the amount of pure alcohol contained in a wineglassful, may be tabulated as follows:

Wine.	Alcohol by Volume.	Sugar by Weight.	Meat Extract by Weight, corresponding to Nitrogen Found.	Pure Alcohol in a Wineglassful.
				Fl. Drachms.
Claret	9	0.25	—	1½
Hock	10	Trace	—	1½
Champagne(dry) ...	10 to 15	Trace to 2	—	1½ to 2
Sherry, dry	19	0.2	—	3 to 3½
„ brown... ..	23	1.0	—	
Port	20	2 to 6	—	3½
Bovril	20.15	10.2	0.5	3½
Lemco	17.26	12.8	0.6	2½
Wincarnis	19.6	18.2	1.2	3
Glendenning's ...	20.3	10.6	0.4	3½
Bendle's	20.3	8.0	2.5	3½
Bivo	19.2	11.5	3.4	3
Vin Regno	16.05	7.4	0.3	2½

THE THERAPEUTIC APPLICATIONS OF RADIUM: METHODS AND RESULTS.

ALPHA RAYS.

By FREDERICK SODDY, M.A.,

LECTURER ON PHYSICAL CHEMISTRY AND RADIO-ACTIVITY IN THE
UNIVERSITY OF GLASGOW.

In view of the fact that the feebly penetrating alpha rays possess at least ten times as much energy as the beta and gamma rays of radium together (Rutherford), it would be of great interest to know definitely whether they have ever been actually employed by medical men in their investigations. The alpha rays of radium are complex, and consist of four types, the most penetrating being absorbed by 3 in., and the least penetrating by 1½ in. of air and by other substances as a first approximation in proportion to their density in terms of that of air as unity. It will therefore at once be seen that it is an extremely difficult matter to employ any covering whatever over the surface of the radium salt if the alpha rays are to be effective. It is true that in France, by the use of certain varnishes, a very thin film of celluloid or collodion is used to cover the radium preparation, but in the absence of any definite physical tests proving that the alpha rays are able to get through this coating, the natural presumption would be that they were completely absorbed. This is one of the questions which it is to be hoped the new radium institutes will definitely and authoritatively deal with; that at Heidelberg specifically offers to medical men the co-operation of trained physicists.

Of the total radiation of radium about one-fourth—the least penetrating of the four types—of the alpha rays come from the radium itself, while the remaining three-fourths of the alpha rays and the whole of the beta and gamma rays come from the spontaneously-formed products of the radium, of which the gaseous emanation is the first in the series. The emanation being a gas and directly concerned in the production of the greater part of the activity of the radium, it is in the highest degree essential that radium salts, after preparation in their final form, should be kept hermetically sealed from the air, as otherwise, by the escape of emanation, much of the activity of the preparation is lost. After being kept for three weeks in a closed vessel, radium attains its maximum, or, as it is also called, its equilibrium activity. Attempts to use the alpha rays, therefore, of necessity involve the risk of loss of emanation, and of the serious

weakening of the activity of the preparation, for no coating thin enough to allow alpha rays to penetrate is likely to be perfectly gas and water tight.

Recently, when asked to prepare a film of radium for a medical man, I abandoned the attempt to utilize the alpha rays, and covered the film with a piece of microscope cover-glass cemented into an ebonite cell. It must be remembered that one of the types of beta rays given by radium are relatively feebly penetrating, and a great saving in efficiency can be effected with a very thin covering even although no alpha rays escape.

The following notes may, however, be of assistance to any one wishing to make the attempt to utilize the alpha radiation.

The first consideration is that the radium salt must be uniformly distributed over as large a surface as possible, as otherwise the greater part of the alpha radiation is absorbed in the salt itself. Radium bromide and chloride undergo a spontaneous chemical change on being kept, part of the acid escaping, with formation first of the hydroxide, and ultimately of the carbonate, insoluble in water, by the action of the carbon dioxide of the air. So that to get the salt into solution a little pure hydrochloric acid should be added to pure distilled water, and two or three drops of this liquid used to dissolve the salt. On evaporation the radium salt remains usually in the form of large crystals, and this defeats the purpose of the operation. But if the whole of the liquid is first evaporated by warming the film on a hot plate and the salt is then redissolved in a drop or two of pure water a second evaporation yields without difficulty a fine homogeneous film of the salt.

As a rough test, to see whether any alpha radiation escapes absorption when the film is curved or coated in any way, one of F. H. Glen's translucent screens of glass thinly coated on the one side with zinc sulphide may be used. On bringing the base-coated side of the screen in the dark immediately over the curved radium preparation, and then alternately inserting and withdrawing a sheet of notepaper, some idea may be obtained, even from commercially prepared radium films, as to whether any alpha radiation is present, for the paper would entirely absorb alpha radiation while allowing the beta radiation to pass with little loss. If the insertion of the paper makes a great difference in the luminosity of the screen it may be inferred that alpha rays are present.

The best time, however, to perform this test is not before three hours after the radium salt is dissolved in water, and within this limit as soon as possible after the film has been got into its final form. At this stage the beta and gamma rays are at their minimum and may, for practical purposes, be neglected, while the residual alpha rays are those of the least penetrating type. Hence, if alpha rays get through when the preparation is tested at this stage it may be concluded that when the radium has recovered its normal equilibrium—after about three weeks—a very considerable proportion of the alpha rays will escape.

The therapeutic action of the alpha rays ought certainly to be tested once for all with a radium preparation from which it has been proved by physical tests that alpha rays can escape. But until this has been done, perhaps the best advice that can be given is that while a covering as thin as is consistent with gas tightness—such, for example, as microscope cover-glass—should certainly be employed, it is better not to risk impairing the activity of the preparation by using a covering previous to the emanation in the hope, which may not be realized, of thereby utilizing the alpha radiation, which, again, may not be therapeutically effective or desirable.

RADIUM CONSIDERED AS A SPECIFIC AGENT.

[FROM OUR PARIS CORRESPONDENT.]

One of the most interesting points in the therapeutics of radium is most certainly its *specific* action. Drs. Wickham and Degrais, in their communication made to the Tenth Congress of French Medicine at Geneva on September 5th, 1908, defined "specificity" as the act by which radium transforms pathological cells and modifies morbid processes into healthy or new tissues no longer presenting any morbid character, and without the production at any

period of an added inflammation at the skin surface, or of the tissues treated.

If the cure of a lesion is obtained only at the cost of irritating it—of inflaming the skin which covers it—then the action has been, not specific, but destructive.

If, on the contrary, the pathological tissues are modified or cured without inflammatory action, then "specific" action will have occurred.

Radium, which has the power, as has been known for a long time, of destroying tissues, is also, according to these observers, capable of acting in a specific manner on certain pathological tissues. The importance of this theory is evident, since it implies that radium possesses the power of curing lesions without inflammation, the integrity of the skin surface being preserved. If, therefore, a lesion is deeply situated and covered with healthy skin, and if this lesion comes within the range of the specific action of radium, it will be possible to effect a cure without the necessity of destroying the skin.

Drs. Wickham and Degrais hold that the following affections are thus "specifically" modified by radium:

1. *Cancer*.—A "vegetating" epithelioma, a rodent ulcer, can be so modified that it disappears and is replaced by good cicatricial tissue, the process being a simple transformation without any added inflammatory action. Regression may be produced also in a cancerous tumour beneath the skin surface, for example, in the breast, without the skin being affected at any time during the treatment. They conclude, therefore, that radium exercises a *specific* action on cancerous neoplasms.

2. *Tuberous Angioma*.—They find that angioma tumours of the lip, tongue, and skin, and vascular tumours situated below the skin diminish and disappear by simple transformation without damage to the skin.

3. *Cheloids* are similarly affected, and may be caused to disappear without irritation.

4. In the same class of cases can be placed chronic pruriginous skin affections—for example, lichenoid eczemas and neuro-dermites; these affections can be modified and cured without added irritation.

The interest of this alleged specific action of radium on the four classes of cases just mentioned (there are others) is enhanced when the very different action of radium on many other affections is considered. As an example, pigmented naevi, tubercle of the skin, fibrous cicatricial bands complicating cicatrices, etc., are affections which, to be cured by radium, must be destroyed. In these conditions another property of radium equally interesting and valuable is called into play—its power of special destruction, a destruction effected without pain, and followed by repair, which cosmetically is satisfactory.

The desired specific effect of radium can be obtained only by the use of special technique and special doses. The first questions to be decided are as to the manner of the application and the dose which does not produce inflammation.

At one time it was thought that the power to act without causing inflammation was the property solely of the rays of great penetrating power, composed entirely of hard beta and gamma rays. It has been proved, however, that it is a mistake to suppose that irritation can be prevented with certainty by cutting off the rays of feeble penetrating power, and that such rays have the power to do no more than irritate, or that the rays of great penetrating power act without irritating or causing any inflammatory action.

In fact, though it is true that the radiations of great penetrating power, consisting of hard beta and gamma rays as obtained by Drs. Wickham and Degrais when they place metallic screens between the apparatus and the tissues, are suitable to produce modifications in the deeper tissues without causing any irritation of the surface, this result can only be obtained on condition that too strong doses are not used, and on condition that the apparatus is not left applied for too long a time. Irritation of the surface results even with these rays if exaggerated doses are used. On the other hand, rays of feeble and medium penetrating power, if applied in special doses, also produce therapeutic effects without irritation. Thus, for example, in chronic pruriginous skin affections, radiations of weak penetrating power produce an effect, and cures are, in fact, obtained without reaction, by the application of the apparatus bare, without filtering screens, using consequently rays of feeble and medium penetrating

power. It is therefore a mistake to say that some rays produce irritative reaction and that others do not. Burns—radium dermatitis—are not, therefore, dependent on this or that variety of radiations, but on the dosage of the radiations.

The following are a few examples to illustrate what has been said on the subject of the specific action of radium—that is, of its power to cure certain lesions without inflammation. The three examples chosen are taken from three different morbid groups, and each comprises the use of a different variety of rays.

I.—*Subcutaneous Cancer.*

This was a case of cancer of rapid evolution in a woman. The tumour, which was of the size of a pigeon's egg, was covered with healthy skin. An apparatus containing 5 cgm. of a radium salt of activity 500,000 was used; it was covered with a sheet of lead 2 mm. thick, ten sheets of paper and a sheet of fine rubber, so that the radio-activity passing through the lead was about 3,000 unities. This apparatus was placed in position on the cancer on alternate nights for twelve hours each time. The application was repeated for fifteen nights, so that in a month it lasted 180 hours. During the two months following the tumour not only stopped growing, but diminished and regressed. At the end of these two months it was only one-sixth of its original size; at no time during the whole period was the skin inflamed.

II.—*Angiomatous Tumour.*

A baby showed on the scalp a large angiomatous tumour raised 2 cm. above the surface. Two apparatuses were selected, and each enveloped in aluminium, $\frac{1}{8}$ mm. in thickness, six sheets of paper, and thin rubber tissue. Thus covered these apparatuses allowed about 20,000 metres to pass, composed of nearly all the medium beta rays, that is, rays of medium penetrating powers. The two appliances were placed on opposite sides of the tumour, facing each other, and applied ten days for twenty minutes each day. Three weeks later the tumour had diminished by a quarter, and the treatment was then begun again in the same way. The treatment was thus repeated three times with intervals of three weeks' rest; the cure was completed without any skin irritation at any moment.

III.—*Chronic Eczema.*

A man aged 30 had for several years suffered from numerous eczematous outbreaks. Until the attack in question the usual dermatological methods of treatment had brought about a cure, but after the last attack the tissues became lichenoid, thick, infiltrated, inflamed, and very pruriginous. For eight months no treatment produced any alleviation.

A varnished apparatus, 30 cm. square, containing 20 cm. of radium salt, with an activity of 500,000—that is, a fourth part pure radium—was used. This apparatus gave a radio-activity of extreme power; it was applied to the face bare without any filtering screen. It might seem probable that an apparatus of such extreme activity placed on sensitive eczematous tissues would cause very great inflammation. This would have occurred if this power had been fully applied—that is, if the duration of the applications had been too lengthy—but the apparatus was only left in contact for three minutes the first day, three minutes the second day, and three minutes the third day on each of the places affected. They then ceased treatment for eight days; then began again a series of three days with three-minutes' application each day, and a third series after another eight days' rest. Thus, during twenty-five days there were nine applications of three minutes on each place affected; not only was there no increased irritation or inflammation, but from the first week the pruritus stopped. In the second week the infiltration of the inflamed tissues diminished, and about the twentieth day there remained almost nothing of the obstinate inflammation from which the patient had been suffering.

If, *theoretically*, certain tissues which have been mentioned above are cured by "specificity," *practically* it is often expedient, in order to gain time, to act by destruction by giving stronger doses. For even if the nature of a lesion calls for "specificity," this "specificity" is only brought into play with certain doses, and if these doses are increased their destructive is added to their specific action.

THE MIDWIVES ACT.

PAYMENT OF MEDICAL MEN.

THE question of the payment of medical men other than Poor Law medical officers called in to attend maternity cases by the midwives has been recently before the Staines Board of Guardians. The attitude adopted by the board in the past has been that the midwives should only call upon the Poor Law medical officers. At the

meeting of the board held on March 16th Dr. W. H. HASKELL moved the following resolution:

That in cases of instrumental and abnormal labour this board, having ascertained on inquiry that the midwife acted in a bona-fide manner in sending for a medical man other than the Poor Law medical officer pay the former a fee not exceeding 1 guinea.

On the suggestion of Mr. GARLAND the words "was justified" were substituted in place of "acted in a bona-fide manner," and with this alteration the motion was carried unanimously.

TRANSMUTATION OF ELEMENTS.

SIR WILLIAM RAMSAY, in delivering his presidential address before the Chemical Society on March 25th, contended that recent experiments conducted in the laboratories of University College made it at least probable that thorium nitrate engendered carbon dioxide, or in other words, that one of the disintegration products of thorium was carbon. Carbon was also stated to have been produced from zirconium, but not from mercury or lead, and what is even more remarkable, from bismuth.

Sir William Ramsay summarized the various arguments in favour of transmutation. These were, briefly, as follow:

1. The subtraction from or addition to an atom of an element of one or more electrons, by virtue of which it is converted into an ion, completely changes the properties of that element.
2. The fact is incontestably proved that certain elements termed radio-active are losing electrons, and are thereby being converted into other forms of matter, which in our present nomenclature have equal claims to be considered elementary.
3. The influence of ultra-violet light on many, if not all, elements is manifested in causing them to part with electrons; it is not, however, thereby proved that they yield other elementary forms of matter.
4. The effect of chemical change is usually manifested in a gain or loss of energy. There is reason to believe that change from one elemental form of matter into another would be accompanied by an unusually large gain or loss of energy, for it is known that the "degradation" of radium is coincident with the loss of a relatively enormous amount of energy. This energy, moreover, is in a highly concentrated form; much energy is contained in small volume, or, what amounts to the same thing, in small mass, using the word in the sense of quantity of matter.
5. It appears that the irregular regularity of the numbers representing the atomic weights can be represented on the hypothesis that the addition or subtraction of definite groups of electrons is the cause of their divergence from a perfectly regular series.

Sir William Ramsay then discussed briefly the experiments of Mme. Curie and Mlle. Gleditsch and suggested as a possible reason why they had failed to transmute copper to lithium was that the conditions of his experiment had not been exactly observed. It was, of course, also possible that in presence of emanation and a copper solution, a trace of lithium was dissolved from the glass vessel which escaped solution in the absence of emanation. Passing from this point he detailed the results of Mr. Cameron's hitherto unpublished experiments on silver nitrate subjected to the action of radium emanation, and showed the results to be negative, the energy of the emanation having been largely expended in separating and depositing a relatively large quantity of metallic silver. He then described the experiments conducted on thorium nitrate. Successive experiments with this substance, undertaken to test the evolution of helium had failed to settle the question definitely, but 270 grams of acid thorium nitrate were found to produce in 173 days 1.08 c.c.m. of carbon dioxide. On the other hand, 300 grams of mercuric nitrate in a little over seven months produced only 0.015 c.c.m. of carbon dioxide.

On treatment of thorium nitrate with radium emanation carbon dioxide had also been found to be evolved. Zirconium nitrate treated with radium emanation had generated carbon dioxide, and a small quantity of the gas had also been obtained from hydro-silico-fluoric acid;

the treatment of lead nitrate with emanation had given a negative result.

A still more interesting apparent transformation was that obtained on treating bismuth perchlorate with emanation. Despite the fact that bismuth belonged to the nitrogen group, carbon dioxide had been generated in very appreciable quantity, but no nitrogen.

Sir William Ramsay described some of the precautions taken to ensure accuracy, and it may be mentioned here that the possibility of the carbon dioxide being produced from grease on the stopcocks of the apparatus was disproved; further, special precautions were taken to exclude the presence of even traces of air. Sir William Ramsay concluded as follows:

"Such are the facts. No one is better aware than I how insufficient the proof is. Many other experiments must be made before it can be confidently asserted that certain elements, when exposed to 'concentrated energy,' undergo degradation into carbon."

LITERARY NOTES.

THE forthcoming double section of the Oxford English Dictionary, which is by Dr. Craigie, contains the words from Ribaldric to Romanite, 3,161 in number. Of these words, 2,747 are illustrated by quotations, and altogether no fewer than 17,677 quotations are given. Comparison shows that the largest number of words recorded in any other dictionary which is at all comparable is 1,366, and of quotations 1,664. Some of the more interesting words are rick, ricketts, rifle, rigmarole, roam, roar, Robin Hood, rhodomontade, and rogue. This instalment will be followed by a portion of S by Dr. Bradley.

In *Chamber's Journal* of March 1st Mr. A. Stodart Walker continues an interesting series of articles entitled "Some Celebrities I Have Known." The present list includes Huxley and William Rutherford, the physiologist. Of the former he says that on hearing Robert Louis Stevenson's depreciatory estimate of the Edinburgh climate he said: "I quite agree with him. I now understand why Edinburgh people are so strong; your summer kills off all the weak ones." Rutherford, whose assistant Mr. Stodart Walker was, he describes as "genial if eccentric." We have no wish to revive the echoes of

Old, unhappy, far off things,
And battles long ago,

but we may be allowed to say that Mr. Stodart Walker seems to have been more fortunate in his personal relations to Rutherford than some other assistants of the distinguished teacher. The stories told of him are mostly "chestnuts" in more or less inept metamorphoses. But the stories told of his encounters with noisy students show that in that rough form of controversy Rutherford was quite able to hold his own.

In the *JOURNAL* of March 6th a summary of observations made by Dr. Elmer E. Jones on himself as to the waning of consciousness under chloroform was given. The following account (which we take from the *Guy's Hospital Gazette*) of the experience of a small boy while under the influence of gas in the dentist's chair may be interesting:

The sensation is very queer, but it is soon over. You dream very many things, and very funny things. I will just give a few facts of my dreams. At first I felt as if I were sinking down in the earth; then I found myself in a cave with 1,000's of little beings generally known as demons, which were very fat. Then one demon eat another, and that one another, and another one eat that one, and so on until only a few very fat ones were left. These turned very thin and very tall until they turned into strings, and then (somehow or other, a way which I can't remember) they multiplied until there were 1,000's of strings (very long). Then my head, which jumped off my shoulders, jumped on top of them, and then snakes appeared and hooked on to each other, and formed (altogether) a sort of large tassel. Then the tassel got smaller and came to a tassel of a railway carriage blind, and all of a sudden I was in a railway carriage. This, however, woke me up, and I was in the dentist's chair with the tooth extracted.

In a recent number of *Public Opinion*, which, by the way, gives week by week in a condensed form the cream of the best that is said by leaders of opinion of all shades throughout the world, there is the following story:

"Mr. President," said a United States Senator, speaking in the House, "I am confident that before our financial physicians

get through with the job they will have the country in the condition of the old man in my State who was very sick. The doctor examined him, and said, 'Old man, you're dying; have you any wish to express before you pass over the river?' 'Yes,' the feeble patient said, 'I wish I had got another doctor.'

Of course the story is secondhand; but that is the special attraction of *Public Opinion*—that one finds in it things one may not see elsewhere. It has been said that one-half of the world does not know how the other half lives; that is equally true of thought. It is the function of *Public Opinion* to let its readers know this with the minimum of trouble to themselves.

Professor Ebstein's *Jahresbericht für innere Medizin*, the first volume of which (1901) is now complete, will in future be issued by Dr. Werner Klinkhardt, publisher, of Leipzig. The second volume, dealing with the years 1902-3, will be ready in the spring of the present year. The volume for 1908 will follow, and the rest in due course. Authors are asked to send reprints of their papers, as far as they pertain to internal medicine, to Oberarzt Dr. Schreiber, 1, Beaumontstrasse, Magdeburg.

At a recent meeting of the Reading Town Council, a letter was read from Dr. Jamieson B. Hurry, in which he proposed to erect a memorial to Henry I. the founder of the famous Abbey of Reading. The proposed memorial is thus described in the *Reading Standard*:

The cross, composed of silver-grey Cornish granite, will rise to a total height of 20 ft., and is designed in such architectural style as is appropriate to the period. The ornamentation of the head consists of Early English foliage on the arms, and of the simplest form of dog-tooth ornament on the circle. Five projecting and carved bosses mark the arms and centre of the cross. The stem, with slightly sunk faces, is divided into sections by a simply-rounded moulding worked into a pattern at intervals. The massive base terminates above in three tiers, and rests on a broad platform of granite with steps on either side. Thus the memorial will rest on a broad foundation which gives a sense of stability to the whole erection. The treatment of the back of the cross will be similar to that of the front; but on the sides of the base will be placed two metal shields bearing the arms of King Henry I and those of Reading Abbey. The inscription will be in lead letters sunk into the granite, and record the foundation of the Abbey by King Henry I in 1121, and the burial of same King before the high altar of the splendid Abbey Church in 1136.

The Abbey received signal marks of favour from successive monarchs, enjoyed the special protection of the Holy See, was selected for great secular and ecclesiastical councils, and for several assemblies of Parliament. By all these and other means prestige, commercial prosperity, and wealth were brought to Reading by the great Abbey at its gate. The time came, however, when the burghers keenly resented the control exercised by the Lord Abbot. Their streams, their mills, their market, their land, were at his mercy, and for two hundred years the galling yoke of a powerful ecclesiastical corporation hampered the development of self-government. It was not until the last Abbot had laid down his life on the scaffold, and the Abbey had been dissolved, that the burgesses obtained from King Henry VIII the privileges they had so long striven for. By the Charter of 1542 the mayor and burgesses were constituted the governing body of the town, with full executive authority and jurisdiction.

MOTOR CARS FOR MEDICAL MEN.

TRICARS.

DR. L. E. PARKHURST (Brackley) states that he has had some years' experience of tricars, and is very satisfied with his present machine—a Phoenix Tricar. It is, he writes, fast, light, comfortable, a wonderful hill-climber, and very easy on tyres, and he has done a good deal of work by its aid since November, 1907. He would advise 'P. C.' to fit on the back-wheel a metal-studded tyre, and on the front wheels good stout, non-slipping tyres, either with a square tread or rubber studs, to avoid side-slip on greasy roads; also to specify copper tops and bottoms to the radiators. Careful driving round corners is absolutely necessary. His tricar is a single-seated vehicle, with bonnet in front to take midwifery and accident bags, and dressings, etc., and the bonnet can be made interchangeable with a front seat.

UNDER the will of the late Mr. Thomas Harris, of Calne, Wiltshire, which has now been proved, the London Temperance Hospital receives a bequest of £2,000.

Medical News.

MR. EDWARD D. MADGE, L.R.C.P., M.R.C.S., has been decorated with the Order of the Star of Roumania.

MESSRS. YEOWARD BROS. of Liverpool have arranged holiday trips to Portugal and the Canary Islands, one of these of twenty-five days' duration starting on March 31st, so as to include the Easter holidays. Messrs. Yeoward inform us that they are desirous of bringing the advantages of these trips to the notice of the resident medical staffs and matrons of hospitals in this country, and would be disposed to offer special terms to passengers from these institutions during the holiday season. Further particulars can be obtained on application to them at 27 and 29, Stanley Street, Liverpool.

THE eighth meeting of the Departmental Committee appointed by the Lord President of the Council to consider the working of the Midwives Act was held at the Privy Council office, on March 24th. The following witnesses attended and gave evidence: Miss Wesley, Matron of St. George's-in-the-East Infirmary, on behalf of the Poor Law Infirmary Matrons' Association; Dr. C. T. Parsons, Medical Superintendent, Fulham Infirmary, on behalf of the Infirmary Medical Superintendents' Society; Dr. Henry Handford, F.R.C.P., County Medical Officer of Health, Nottinghamshire, on behalf of the Health Committee of the Nottinghamshire County Council.

THE report of the Leper Home at Tungku, South China, for the year ending September, 1908, contains a variety of interesting references and photographs. The numbering of the lepers by the magistrate, which took place at the end of 1907, is first described and illustrated by a photograph. The magistrate decided to divide the subsidy equally between the lepers and their descendants, but sixty graduates and more than a hundred shopkeepers signed a petition of protest and in favour of giving the Tungku home the subsidy originally destined for the lepers. The numbering was not carried out without many useless comings and goings and wasting of time and energy, modes of doing business so dear to the governmental official mind, whether tortuously working within the skull-box of Mandarins or Far Cathay or of our own gentlemen with buttons and peacock feathers. The philanthropists in our midst will be interested to know that, in the words of the report: "The long hairy appendage of the Chinese being a great hindrance to cleanliness, a reward of 10 cents is offered to those who shave clean their heads. Fifty-six have already made the sacrifice of their cue." In the medical part of the report additional evidence, if that be necessary, is afforded that contagion is the factor in the spread of leprosy, and that heredity, as has been known for some time, plays no part. Nasta was tried in two cases, but the results do not point to anything worth noting here, as further trial must be made. The report is compiled by Dr. John E. Kuhne.

WEDNESDAY last week was St. Patrick's Day, and, in accordance with established custom, the Irish Medical Schools' and Graduates' Association duly recognized the festival by a dinner. This was held at the Cecil Hotel on Thursday evening, and the pleasant practice of including ladies among the guests was again followed. The assembly numbered altogether over 200 persons, Dr. F. A. de Thierry Mouillot, President of the Association, who was in the chair, being faced by Drs. J. J. Macan and Alexander Macdonald, Chairman and Vice-Chairman of Council respectively; Dr. M. J. Bulger, Honorary Treasurer; Drs. T. Hobbs Crampton, W. Douglas, and G. W. Dawson, the Honorary Secretaries; and Dr. Morgan Dockrell. The toast list was interspersed with songs, and the proceedings were prolonged until a late hour. "Our Defenders"—a toast habitually and naturally well received by members of an association so largely represented in the naval and military services—was welcomed on this occasion even more cordially than usual. The disquieting disclosures which had just been made in the House of Commons were fresh in mind, and of this circumstance Dr. J. A. Macdonald, the proposer of the toast, made impressive use. The special interest of the evening, however, lay in the presentation of the Arnott Medal to Lieutenant J. Smith McCombe. He is a Lieutenant in the Royal Army Medical Corps, and when stationed at Millbank last year made determined efforts to save a lad who had fallen into the river, diving and redvining in the muddy depths until thoroughly exhausted. Of this gallant feat an excellent account was supplied by Dr. J. J. Macan, who introduced Lieutenant McCombe to the Chairman, and also gave a brief history of the Arnott Medal and its earlier recipients.

SATURDAY, MARCH 27TH, 1909.

NATURE HEALERS IN GERMANY.

HISTORY repeats itself. And it repeats itself not only out of the past, but by producing similar situations in several distinct directions in the present. The vagaries and peculiarities of our own antivivisectionists would appear to any one who does not know what is going on elsewhere as so extraordinary that no other group of human beings would be likely to have recourse to similar tactics. But as there are strange people among us, whose methods of reasoning appear to the ordinary mortal to be so illogical as to suggest some definite psychical defect, so are there in other lands persons whose sole and only reason for differing from the majority seems to be that the opinion to which they take exception is that held by those best qualified to arrive at a correct conclusion. This spirit of opposition, however, is often based on the chances of pecuniary gain which it offers, and the desire for notoriety. For several months the movements of the "Nature healers" have been chronicled in the *Gesundheitslehrer*, and we have been struck by the similarity between this movement and the one to which reference has already been made. It is not our intention to discuss the truth or fallacy of some of the doctrines preached by Pfarrer Kneipp or by "Prophet" Bilz; nor need we refer to an extraordinary novel, written by Bilz, styled *In One Hundred Years*, in which the author depicts, with a fine frenzy, the future generation of mankind, after the doctrines of Bilz have revolutionized the whole of hygiene, have banished disease, and have led to wonderful and far-reaching "reforms" of an ultra-socialist type.

These things are interesting from a psychological point of view, but of greater interest for the present is the method of attack which the Nature healers adopt. From the *Gesundheitslehrer* we learn that the number of Nature-healing societies has diminished from 908 to 878. At the same time the membership has increased from 130,909 to 134,995. In the case of the antivivisectionists the number of societies is still growing, but we doubt whether the total membership is also increasing. The German movement, however, exhibits greater union. In September, 1908, the various societies held a conference, and there determined to oppose a bill before the Reichstag for the suppression of quackery. A careful study of this bill shows that the means proposed to suppress the evil are so moderate as to be in the opinion of many not nearly strong enough. In any case, the Nature healers feel themselves hurt by legislation which attacks quack practice. The conference determined to canvass the members of Parliament personally; to heckle candidates at elections; to publish articles in the local newspapers; to conduct correspondences in "hostile" newspapers, fighting the cause; to collect the literature from the newspapers; to issue leaflets; to organize co-ordination between societies friendly towards quacks, and to train debaters. With these powerful weapons they will storm the Parliamentary

citadel. The societies have their own journals. The chief of these is the *Naturarzt*, a journal which the *Gesundheitslehrer* does not hold in high esteem. The *Naturarzt* has recently had a dire misfortune. It, or rather the union which it represents, was compelled to get rid of the editor, one Gerling, who, while preaching drugless treatment through the medium of his journal, was running quack remedies through other channels. His departure, it was considered, became necessary, when it was discovered that, while lecturing on "sexual instruction," he caused to be placed on each seat a copy of an advertisement of his book on a new method of treatment which recommended the use of a substance called ichtthyl-javol and other similar medicaments. He was once a trusted leader, a guiding spirit, but since his exposure his former friends can find no words too hard in which to condemn him and hold him up to derision. The Nature healers have their members of the Reichstag, as the antivivisection movement has M.P.s, and the reputation of these members among their colleagues is very similar. In criticizing the bill for the suppression of quackery a Nature healer attempted to show that medical men adopted methods which the bill is intended to prohibit, and of which the Nature healers are very fond, such as treatment by correspondence and by means of secret remedies. The *Gesundheitslehrer* states as the result of inquiry that three medical men in Germany out of a total of about 30,000 do carry out this practice of treating patients without seeing them, and using drugs of which the composition is secret.

A further striking similarity is to be found in the artificial demand for the institution of an independent, unbiassed investigation. One spokesman of the Nature healers, Herr L. vom Rheine, suggested that Nature healing should be allowed to prove its capabilities before a mixed lay and medical committee, patients being treated by "natural" methods in hospitals. It need not be supposed that he expected this suggestion to be accepted, but it is the kind of rhetorical flourish with the like of which we have become painfully familiar. Herr vom Rheine seemed to fear that if his test were not applied Nature healing would disappear; but, as the *Gesundheitslehrer* points out, there is unfortunately little chance of the movement disappearing, for the whole world of charlatans is too securely protected. The Nature healers, like their brothers the secret remedy quacks, grow rich by blatant advertisement, and the plucky attempts to check their sway on the part of journals like the *Gesundheitslehrer* are able to divert only a small stream of the torrent which sweeps away the hard-earned savings of the credulous middle and lower classes.

A THEORY OF HYSTERIA.

A FEW weeks ago we referred to the views held and eloquently expounded by Dr. Babinski with regard to the great and in his opinion incongruous mass of phenomena commonly designated hysterical. Dr. Babinski¹ quotes with approval an unpublished remark of Lasègue's, that "hysteria is the basket into which we throw the papers which we do not know how to classify." Doubtless there is even yet much truth in this, though with the rapidly increasing number of differential criteria—to which Dr. Babinski has himself made many notable additions—this somewhat ironical observation must

¹ Démembrement de l'hystérie traditionnelle, Pithiatisme. By J. Babinski. Paris: Leys.

become less applicable day by day. At the same time it seems possible that Dr. Babinski has carried his destructive criticism too far, and has constructed, under the term "pithiatism" (*πειθισμός*, persuasion; *élaros*, curable), a classification which, though undoubtedly suitable for certain groups of cases, is not only arbitrarily limited, but fails by not explaining the terms of which it is composed.

As we have already said, Dr. Babinski contends that the category of hysteria has been improperly extended by erroneous diagnoses—that is, either by subsuming under this head cases of organic disease, or by underestimating the part played by deceit, or by a confusion of hysteria with other functional neuroses. All of these statements may be accorded a ready acquiescence. There can be no doubt that in the past, inevitably, from the lack of important diagnostic signs, cases of organic disease have been classed as hysterical, just as cases of hysterical nature have often been considered and treated as of organic origin. It appears equally certain that medical men and their patients' relatives have often been imposed upon by conscious frauds and simulators, though this is with us much less a matter for self-accusation than amongst our neighbours across the Channel, to many of whose extreme views Dr. Babinski's teaching affords an admirable corrective. Incidentally, it may be mentioned that the difficulty of detecting the simulation of hysteria—almost impossible in persons who have gone the round of the hospitals and have been involuntarily trained by the medical men who have given clinical demonstration—is increased by the fact that many of the symptoms of hysteria are such as would naturally occur to one who wished to assume the disorder, and that to some extent the parts or functions of the body engaged are affected, not according to their anatomical relations, but in harmony with the ideal representation of these parts or functions in the minds of the subjects. To the generality of people, for instance the hand stops at the wrist, and thus it is found in hysterical anaesthesia of the hand that the loss of sensibility is determined by this popular conception and does not follow the nervous distribution.

Upon what, then, should the diagnosis as between true and deliberately malingered hysteria depend? Dr. Babinski says at once, "upon reasons of a moral order," and immediately adds, somewhat inconsequently, that "the failure of psychotherapeutic measures, carried out under good conditions and with perseverance, should incline one to the hypothesis of simulation." This latter opinion may or may not be true, but, for "reasons of a moral order," we would rather substitute the conformity or non-conformity of the symptoms in any case with the clinical phenomena which have been definitely ascertained to be characteristic of the disorder, and particularly with the laws which have been deduced from the manner and order of appearance of these phenomena. Take, for example, a typical hysterical phenomenon—that of retrograde amnesia following somnambulism. Here, as Janet has pointed out, the loss of memory bears not only on the period of somnambulism, but also on the event that gave rise to it and to the facts and feelings related to it. Obviously, no malingerer, unless expert in the matter, would assume symptoms in conformity with this observation, which furnishes thus a definite diagnostic aid. In a similar way the clinical characters of the varied signs and symptoms of this disorder—amblyopia, hemianopsia, anaesthesia, palsy, and so on—

supply, it appears to us, the essential criteria, and not, however useful in their place, reasons of a moral order, such as a desire for sympathy or other gain.

Doubtless, also, Dr. Babinski is right in maintaining that other so-called functional neuroses are frequently confounded with hysteria. This is only to be expected in a region so obscure that hardly any two authorities are agreed upon the first and all-essential step of definition. The number of discarded definitions of hysteria must already be considerable, but, whatever the fate of the awkward word "pithiatism," coined by Dr. Babinski, his definition of hysteria as "a well-defined neuropathic state produced by suggestion and curable by persuasion," has at any rate the merit, by restricting the connotation of the term to a definite group of cases, of excluding from the category of hysteria many neuroses often, and perhaps wrongly, included. Is this increased clearness of definition, however, an absolute gain, or is it not obtained, as suggested above, by fixing an arbitrary standard and by the sacrifice of other forms of disorder which, though neither produced by suggestion nor yielding to persuasion, are yet identical in their symptoms with the forms classed by Dr. Babinski under pithiatism? Dr. Babinski himself raises this question when he asks, "Is the symptomatic aspect of the phenomena to which suggestion gives birth specific, or may it not belong also to a functional malady having a different mechanism from that of suggestion?" It is, he says, "still impossible to resolve this question in a definitive fashion," and, in admitting his inability to answer this question, he admits also the conventional character of his classification.

Whilst classifications are often of necessity conventional, definitions of disease should always, if possible, be what logicians term real and essential; they should go to the root of the matter. It is evident that Dr. Babinski's definition is not of this order, but is purely nominal. Waiving here any discussion of the second term of Dr. Babinski's definition, which on the face of it is not explanatory but merely a definition by result, and regarding only the statement that hysteria is produced by suggestion, it is apparent that this statement, even if it be true, only shifts the ground of the problem, and does not settle it. For what is suggestion? What determines suggestibility? These questions Dr. Babinski does not explicitly discuss in the pamphlets in which he has set forth his views on hysteria, but it is important to recognize that for him the phenomena of hysteria and of suggestion—excluding, of course, conscious imposture—are the results of processes of unconscious simulation or "demi-simulation," and that the subjects of hysteria, as he seeks to define it, are actors under the influence, however dimly perceived by them, of interested motives; are, in fact, self-deluded, unconscious frauds. But if this be so, we may fairly ask why it is that hysterical aphasia is often accompanied by right-sided hemiplegia. And if, as Dr. Babinski teaches, anaesthesia and many other hysterical stigmata are suggested to the patient by the examining physician, why are they suggested in some and not in all?

One more point raised by Dr. Babinski cannot be passed over. For long it has been accepted that shock, and particularly violent emotional shock, is amongst the most important factors in the causation of hysterical disorders. Dr. Babinski in strictly logical harmony with his views, maintains that shock is a minor factor, playing an infinitely less important

part than imitation; and, conversely, that when a patient, functionally paraplegic, recovers under the influence of a fright—say of his house burning over his head—it is not the temporary emotion, but the ideas of recovery, previously suggested, which are operative at a moment when his attention, up to that moment concentrated on his paraplegic limbs, is temporarily distracted. When, later, the idea of his impotence returns, the knowledge that for some instants he has been relieved is sufficient to persuade him of his recovery.

This explanation of Dr. Babinski's—constructed, one may suspect, with a careful regard for his theory—is ingenious, but the attempt to reduce hysterical phenomena to imitation, unconscious or semi-conscious, to expunge their affective origin, and to give them not only an ideal content, but a solely ideal causation, is only to come back, as Janet says of Bernheim's remark that "the hysterical realizes 'his accident just as he conceives it,' to a kind of contemptuous accusation against the patient, and, it may be added, to rob the disorder of any reality. The toothache, however, which vanishes before the sight of the forceps, has none the less an actual basis: and, as MM. Mathieu and Roux have said of hysterical vomiting, the essential characteristic 'is less the fact of accepting some idea or other than the action 'exercised by the idea on their stomachs or intestines.' That is, as Freud has pointed out, there is an unduly heightened lability of somatic outlet, or bodily expression, of certain ideas which for the time being hold the mind. This feature, whose origin need not be discussed here, is characteristic, it is true, of both hysteria and hypnosis, but can hardly be considered to be satisfactorily explained by a theory of imitation or demi-simulation.

The inherent connexions of hysteria and suggestions are patent, and the light which the study of hypnotic phenomena has thrown upon hysteria must be gratefully admitted. But to concede this is not to accept the statement that hysteria and suggestion are always the same processes, at any rate, until "suggestion" and "suggestibility" have been explained and defined with a much wider significance than seems to be attached to them by Dr. Babinski. Still less is it to admit that hysteria and suggestion are identical in origin, whilst the term "pithiatism" does not appear happy in its application either to the wretched beings who were burned as witches in the Middle Ages because they exhibited the cutaneous anaesthesia known as the "Devil's Claws," or to many of their successors of to-day.

STREET AMBULANCE SERVICE FOR LONDON.

THE Committee appointed by the Home Office to recommend a scheme for the extension of the street ambulance service in London has reported in favour of empowering the Metropolitan Asylums Board to establish and maintain a non-infectious service of rapid ambulances for the conveyance of persons suffering from accident or illness. The Local Government Board is to make regulations to ensure complete separation of the new service from the existing service for infectious cases.

The subject was one in which the late Mr. Reginald Harrison took a great interest, and to which, as President of the Metropolitan Ambulance Association, he devoted much time and attention. The result of his experience in Liverpool, of his investigations of the methods employed in America and on the Continent,

and of his study of the special problems presented by London was to lead him to the conclusion that as the police are so intimately concerned with the immediate handling of street casualties it would be simpler to place the ambulance service in London under their direction. Many of those who have had practical experience in other cities, and have made themselves acquainted with the conditions existing in the metropolitan area have arrived at the same conclusion. The Committee has not adopted this view, mainly on the ground that it thinks that the system of rapid ambulances should be made available for emergency cases occurring in private premises among the poorer classes, not paupers; but it advises that the Asylums Board, in establishing and conducting the extended service, should act in consultation with the Commissioner of Police, especially with regard to the choice of sites for any new ambulance stations, and their staffing and equipment, and as to the provision of the requisite signalling apparatus. The difficulty created by the fact that the Metropolitan Police are concerned with a much larger area than the Asylums Board may, it is thought, be met by authorizing the use of the non-infectious ambulances outside the county of London on payment to the Board out of the Metropolitan Police Fund of reasonable fees. Further, any board of guardians that possesses a rapid ambulance is to be empowered to arrange with the Commissioner of Police for its use on agreed terms approved by the Local Government Board. The Committee also recommends that in selecting sites for ambulance stations regard should be had to (1) the number of accidents habitually occurring in the neighbourhood, (2) the probable distance between the scene of the accident and the nearest available hospital, and (3) the extent to which the locality is at present effectively served with wheeled litters.

It is thought that the rapid ambulances might be either horsed or motor, and that the number required should be determined by experience, being gradually increased as necessity is shown. The Committee does not recommend the extension to the whole of London of the special signalling system in use in the City, partly on the ground of cost and partly because it is believed that a proper utilization of the best available telephonic communication will suffice.

Sir William Church told the Committee that the experience at St. Bartholomew's Hospital proved that the first aid administered by the City police is excellent, and by the Metropolitan Police not bad. The Committee accepts this opinion, and recommends that a police officer should accompany the rapid ambulances, which should be reserved for serious cases, and that every police officer should attend the advanced course of instruction in first aid as part of the regular discipline.

The report is signed by all the Commissioners—Sir Kenelm Digby, the Earl of Stamford, and Sir William Collins, M.P.; but the last named adds a note recommending that the duty of establishing and maintaining the proposed service should be entrusted to the London County Council, which has framed a scheme and sought powers to carry it out. This may seem the more logical course, but there are administrative difficulties in the way, and certain constitutional questions might conceivably arise. The scheme recommended is, in fact, of the nature of a compromise, and is probably not such as would have been devised had the Committee had a clean slate; but, apart from other

considerations, it was bound to recognize the fact that, though the street ambulance service in London is very deficient, progress has been made in recent years, and that in particular there are some 400 wheeled litters now in use by the police. The Committee recommends that these should be kept in commission for the present at least, and superseded gradually by rapid ambulances as funds become available.

Of the need of the provision of rapid ambulances for the institution of a system generally more effective there can be no doubt. The number of street casualties in London is increasing—there were 10,540 in 1904 and 17,055 in 1907, an increase of 62 per cent. in three years; moreover, the number of serious accidents increased even more rapidly from 155 in 1904 to 283 in 1907, an increase of 80 per cent. At present cabs and vans are frequently used to remove persons injured or taken suddenly ill in the streets, and it is not surprising to read that in nearly a fourth of 427 cases taken to hospitals definite fault was found by the medical staff with the manner in which the patient had been brought to the institution, and in 57 cases the patient's condition was considered to have been prejudiced thereby.

MEATY WINES.

A GENERATION ago it was not uncommon for the benevolent practitioner of domestic medicine to prepare a tonic wine by putting a few grains of quinine into a bottle of cheap sherry or orange wine. The idea presented certain attractions, and as often happens with regard to other domestic remedies, it has been taken up by manufacturers, and at the present time there are a very large number of medicated wines and alcoholic preparations, bearing various fancy names, upon the market. In some cases the addition to the wine consists of a drug such as quinine or coca; in others, of meat or malt extracts, either alone or in combination. With regard to the meat wines, the chief objection on public grounds to their use is that persons who might not otherwise be disposed to take a glass of sherry or port at odd times during the day may be induced to take a wine containing as much alcohol because of the nourishing constituents which have been introduced into it by the addition of meat or malt, or both. Without labouring the question whether meat extracts can properly be called nutritious or not, it may be pointed out that by the use of these meat wines the alcoholic habit may be encouraged or established, and that it is a mistake to suppose that they possess any high nutritive qualities. Samples of seven meat wines, including, it is believed, all those most extensively used in this country at the present time, have been submitted to analysis, and the detailed results will be found at page 795. It will be seen that in all instances the percentage of alcohol present approaches that commonly present in sherry or port. Some are probably made from sherry or other wine of similar type, and others, as their vendors profess, from port. The addition of malt extract in the quantities indicated by the analyses would, of course, lower appreciably the relative percentage of alcohol in the meat wine as compared with that in the sherry or port from which it was made. The same remark would apply to the meat extract if, as is probable, it is first dissolved in a little water before it is added to the wine. The beef and iron wine contained about 2 grains of iron in a wineglassful. In the meat wine stated to contain quinine, the amount of that drug present must have

been very minute, for it was too small to be weighed or identified, or even to respond to so delicate a test as the formation of a fluorescent solution.

AUTO-INOCULATION VERSUS HETERO-INOCULATION.

IN an interesting and suggestive paper read before the Medical Section of the Royal Society of Medicine on March 23rd, Dr. E. C. Hort developed the conception that in an infective disease not only does the infecting bacterium elaborate toxins and other substances, but derivatives of the cells and tissues of the infected organism are also formed, the disease complex being due to both these factors. It is further suggested that the cellular and other derivatives of the infected organism may be as important as the bacterial products, both in the causation of the disease and for the induction of immunity thereto. With regard to the importance of the cellular derivatives in the causation of some of the phenomena of disease, an example is met with in the formation of a circumscribed abscess by a localized bacterial infection. The changes occurring in the tissues at the site of infection result in the degeneration, death, and disintegration of numbers of cells; and, from what we know of the results of the artificial injection of cells and cellular derivatives, the discharge of such cellular products must cause some form of response. The destruction of tissue ending in the formation of the abscess cavity is probably largely due to proteolytic ferments derived from the disintegrating cells. The products of cellular disintegration, which include various enzymes, may be pyrogenetic, for there is evidence to show that aseptic abscesses may follow burns, and may also be pyrogenetic, since the formation of an infarct, an internal hæmorrhage, and a simple fracture may all be followed by rise of temperature and general disturbance. Further, Welch¹ in his Huxley Lecture delivered in 1902, pointed out that in the process of infection various cytotoxins may be formed, the parasite contributing amoebotoxins, and either the parasite or the host contributing complements, for these cytotoxins. There is a great deal to be said, therefore, for Dr. Hort's contention that when Nature cures an infection, she converts tissues and bacteria into auto-inoculating agents, and thereby incites both cellular and bacterial restraint, and that to provoke the latter, as is done in vaccine treatment (hetero-inoculation), and ignore the former is too often to aim at half and expect the whole. On the other matters dealt with in the paper—the use of the evening temperature as a measure of the course of infection and of immunity, the advantages of artificial auto-inoculation, and the value of the antitryptic index,² etc.—we have no space for comment, but they are well worthy of study.

THE OPHTHALMIC SPECIALITY.

UNDER the title *Oculist and Aurist, or Oculist and Physician—Which?* Lucien Howe, the great American authority on the ocular muscles, discusses the vexed question as to whether ophthalmologists should take up the throat, nose, and ear as well, as often happens both in America and in many English towns, or whether it would be better for them to be expert in ophthalmic surgery and in general medicine (*Ophthalmology*, January, 1909). He urges that there is little connexion between the ear and the eye, and that life is too short for one man to master the enormous literature appertaining to any one of these organs. On the other hand, medicine and ophthalmology have much in common, and Howe thinks that if the ophthalmologist fails to cure a headache by correcting the ametropia and

¹ BRITISH MEDICAL JOURNAL, 1902, vol. ii, p. 1105.

² See the BRITISH MEDICAL JOURNAL, vol. i, 1909, p. 489.

heterophoria he should be prepared to examine the condition of his patient's digestion, to give a test meal, and determine the amount of free hydrochloric acid. He should also be able to enter fully into the subject of renal disease, and in this no doubt he is to some extent right. He must have a good knowledge of general medicine, and an expert knowledge of neurology, but he should most certainly refer the patients to a physician if in a hospital, or to their medical attendant if private patients, for the diagnosis and treatment of diseases outside his own speciality. On the other hand, although the ear and the eye have little in common, the eye and the nose are closely related, and during the last few years the closeness of the relationship has been more clearly perceived; so close, indeed, is it that it may be doubted whether a man who cannot make an adequate examination of the nose can reasonably be regarded as a fully qualified eye expert. In every case of lacrymal obstruction it is absolutely necessary to examine the nose, and in retro-bulbar neuritis and inflammatory processes in the orbit it is even more essential. The ophthalmologist need not treat nasal disorders, but he ought to be able to diagnose them. Howe also overlooks two facts, both bearing on the unpleasant truth that most ophthalmic surgeons have to make a living. One is that if he dabbles in medicine he cannot expect the support of the general practitioner. He should never even, if he can avoid it, write a prescription; if the patient require an antisyphilitic course, he should refer him to his medical man, and the same is true as regards tonics and other drugs. The other condition is that in many towns a man can make a living if he practise as an oculist, aurist, laryngologist, and rhinologist, but not if he confine himself to the throat, nose, and ear alone, or to the eye alone. So we should give the opposite answer to Howe's question. By all means, if he can, let the specialist be a specialist in one branch, but, if he must take up the subjects, let it be ophthalmology and oto-laryngology rather than the eye and general medicine.

OLD AGE PENSIONS AND MEDICAL RELIEF.

ON more than one occasion we have pointed out difficulties that might arise as regards the medical care of the aged poor when old age pensions came into force. From the beginning it was obvious to us that these State pensioners would of necessity require some kind of State assistance as regards their medical needs, and we pointed out that parochial medical officers would probably be called upon to attend these old people in their homes, whom under other conditions they might have treated in workhouse infirmaries. As time goes on this is pretty sure to entail an extra amount of work on the Poor Law medical officers, which the authorities must in justice recognize and reward by increased emoluments. When the Act was under discussion it was over and over again stated that medical relief would not disqualify for a pension, and consequently it ought to be generally known that such relief cannot by itself cause the forfeiture of a pension when applied for by a pensioner. This is not, however, generally understood, as is proved by a very pathetic case which has come under our notice this week, in which a poor old woman of 76 died at Warwick without medical aid. At the inquest it was stated that she would not send for the Poor Law medical officer for fear of losing her pension. The coroner added that he had known of other similar cases, in which this fear had prevented pensioners from applying for medical relief. There is no legal foundation whatever for this fear, as is shown

in our Parliamentary Notes by an answer given in the House of Commons on this very case. The fact that the fear exists is, nevertheless, a serious matter, and one which the Local Government Board and all local authorities should take steps to dissipate. There has always been a horror of Poor Law relief deeply engrained in the minds of many of the best of the poorer classes, and in the past tragedies from time to time have been recorded in which this kind of exaggerated self-respect on the part of poor old people has been wrongly persisted in to the end of life. Death has been preferred to the help of the Poor Law. This was always wrong. It is still more wrong now the State has created pensions for the old workers, that they should be deterred by an unfounded fear of loss from accepting the aid in illness which the State affords. The medical profession, never lacking in generous charity, will, no doubt, look after poor old people with the same readiness as in the past, and the members of the Poor Law Medical Service on which the duty is naturally thrown will, we are sure, equally meet the new demands that are sure to arise. On the authorities, however, rests the responsibility not only of making it known that medical relief is available without any risk of loss of a pension, but also of organizing the parochial medical service for this most humane and praiseworthy duty.

KISSING THE BOOK.

THE movement in favour of the use of the Scottish method of swearing witnesses—which in English courts first became legal in 1888—has been long and slow, but during the past few months has made very distinct progress. Carried on at first chiefly in the pages of this and other journals of like kind, it at length attracted general attention, so that many more people than formerly began to appreciate the force of the objections raised to the English form of oath, and to be interested in the success of the movement. Some three months ago, indeed, certain judges of the High Court, realizing the importance of the question, indicated their intention of facilitating swearing by the Scottish method in their own courts. It would be well that those specially interested in the matter should keep themselves informed as to the extent of the success which has been already attained. It is clear that this is not always the case, and, as an example of the kind of oversight in question, may be quoted a letter, dated from the Law Courts, which appeared in the *Times* on March 18th. Having quoted a resolution in favour of abolition of the English form of oath, recently passed by the Liverpool Medical Institution, on the motion of Mr. F. W. Lowndes, one of the earliest and most active of those who have moved in this matter, the letter urged upon all medical societies to take the same step, on the ground that this would be more likely than anything else to awaken some one who had the power and was in the position to initiate in Parliament the change required. The use of the word here italicized makes it clear that the writer, in spite of his interest in the subject, is quite unaware that there is no need for this matter to be initiated in Parliament, seeing that there is already on the statute book an Act legalizing the Scottish form, and that a bill, whose stated object is to make administration of the oath by the uplifted hand universal and to enable courts to administer oaths in this form to all persons who do not specifically object thereto, was introduced in the House of Commons at the beginning of the current session. Its sponsor is Mr. Bramson, other names which appear on it being Mr. Godfrey Baring, Sir George Scott Robertson, Mr. Gulland, Sir Thomas

Whittaker, Mr. Wedgwood, Mr. Younger, Sir John Baker, Sir Luke White, and Mr. H. G. Montgomery. It is a bill of four short clauses, and having already passed its second reading is now in the hands of the Standing Committee of the House of Commons. Whether it will become law is, of course, uncertain in the present state of public business, but at present all the presages seem in favour of the desired reform being effected within a reasonable period. Should it be brought about by this particular bill, "kissing the book" will certainly within a very short time become a rare event, even though the formula for administering the oath will not, necessarily, be absolutely identical with that employed in Scotland, where the words of the oath have to be recited by the witness himself. The bill apparently intends that this shall usually be the case in the English courts, but makes it permissible also for the court or its officer to recite the words of the oath, the witness holding up his hand and giving his assent thereto. Finally it may be mentioned that those who have hitherto not paid much attention to the subject will find a fairly complete review of the considerations involved at page 175 of the issue of the *BRITISH MEDICAL JOURNAL* for January 16th, 1909.

WESTERN MEDICINE IN CHINA.

A MEETING, attended by Sir Robert Hart, the Chinese Ambassador, the American Ambassador, and many other important people, was held at the Mansion House on March 16th, in furtherance of the objects described in a circular issued by a body called the China Emergency Committee; and a resolution was adopted calling for the provision of a sum of at least £100,000; that sum being, it is calculated, the minimum necessary for carrying out the following objects: (1) The establishment in four important centres of population in China of colleges for the training of Chinese students in Western medicine and surgery, the institutions uniting the Christian churches at work in China without sacrificing their various denominational principles; (2) the provision in as many centres as possible of "normal" training for Chinese school teachers and pastors on the same basis of unity as the medical colleges; (3) for the publication in Chinese of the best Western literature suitable for medical, normal training, and theological colleges, to assist the Christian literature and tract societies already at work in that quarter of the globe. If the eloquence and importance of the speakers to the resolution at this meeting are any criterion, there can be little doubt that the sum in question will be collected, and the project to that extent succeed. Whether it should really receive the support of the public at large is quite another question, and for our own part, as our co-operation has been invited, it seems right to observe that a fair degree of progress has already been made in the teaching of Western medicine to the Chinese without assistance such as that now in question. Apart from provision for men, there are even places at which medical women are educated. Hitherto, however, the success of these institutions has been retarded, as was pointed out by Miss L. E. Saville in a paper recently read by her at a meeting of the Association of Medical Women, by the lack of adequate preliminary education among the students of either sex who seek and obtain admission to these schools of Western medicine within the area of China. When the Chinese authorities have taken steps to secure that would-be Chinese practitioners of Western medicine are in a position to profit by the medical education already afforded, the progress made will doubtless be much greater. Mean

time, it may be observed that the sums received by missionary societies are so large, and the Chinese have on many occasions shown themselves so ready to assist by large sums any educational project which they deem of value to their countrymen, that it is not easy to understand why it should be necessary to make a special appeal to the public of these islands; its philanthropy is already being tested to the full by much more crying needs at its very door. At the present moment, if not always, the authoritative calls on that form of charity which does not commence at home should be scrupulously limited.

SLEEPING SICKNESS.

DR. MORRIS, Acting P.M.O. of the Nyassaland Protectorate, continues the diary¹ issued at intervals by that Protectorate. He quotes Drs. Kinghorn and Montgomery as stating for North-Eastern Rhodesia that the distribution of *Glossina palpalis* has been fairly well determined to be confined to: (1) A part of the Luapula river; (2) a small stretch of the Kalungwisi river about ten miles in length; (3) Lake Mweru, and for some distance up its tributaries the Luao and the Luchinda; (4) Lake Tanganyika, round the whole extent of the British shore, and up its principal confluent, the Lovu river, for a distance of from fifty to sixty miles of its mouth. They further report two interesting observations on the habits of this fly: (a) a certain degree of adaptability to its conditions—for example, the shores of the lake are formed of "rocky beaches with small scattered patches of 'bango' reeds, presenting a picture which differs very materially from what has been considered to be typical *palpalis* country—that is, heavily-wooded banks, affording abundant shade. The fly could always be found in even the scantiest collection of "isolated reeds, and was frequently seen basking in "the sun on rocks at the water's edge." (b) A certain degree of seasonal variation in its occurrence. The first observation is of great importance, and should be specially noted by those working in Uganda. Will the fly adapt itself to cleared areas there? The Sleeping Sickness Bureau also publishes a small pamphlet, on *How to Avoid Infection: With an Account of Glossina palpalis*. Diagrams of different flies (enlarged) are appended. It would be a great advantage to put pictures of the natural sizes of the flies beside the enlargements, as otherwise the reader gets a very erroneous idea of their real size.

POLICE SURGEONS AND CORONERS' INQUIRIES.

SOME well-merited compliments to police surgeons in London were paid by Mr. Schroder and Mr. Curtis Bennett on the occasion of the annual dinner of the Metropolitan Police Surgeons' Association. The former expressed a belief that it would be an advantage to the public if divisional surgeons were appointed medical referees in cases in which the coroner desired a professional opinion in addition to that of the medical attendant on the deceased, and Mr. Bennett dwelt on the high value of the assistance given him by these officers as witnesses at Bow Street. In the course of the evening the history of the association during the past twenty-one years was briefly related by its senior honorary secretary, Dr. Owen Fowler. Much of the good work done by its council dealt with matters of a confidential nature, and could not appear in the annual reports. No divisional surgeon should hesitate to send to the council a statement of any difficulties encountered, for it was always ready to assist members

¹ Nyassaland Protectorate: Sleeping Sickness. Diary Part VI. By the Acting Principal Medical Officer, Zomba. Printed by the Government Printer, 1908. London: Sleeping Sickness Bureau, Royal Society, Burlington House, W. 1909.

and to endeavour to improve their position. At the Departmental Committee now sitting at the Home Office the association intended to prove that when special experience in connexion with necropsies and giving evidence, either supplementary to that of the medical man in attendance on the deceased or where no medical man had been called in, was thought necessary by the coroner, a divisional surgeon should be appointed to act as medical investigator. As a matter of fact, such work was already being done by divisional surgeons all over the metropolitan police area. At times the services of a pure pathologist might be required in addition, but this was quite exceptional. This dinner, at which the retiring president, Dr. Spurgeon, took the chair, was preceded by the annual meeting of the association, when the following were appointed officers for the year: Mr. A. F. L. Dorin, president; Dr. C. P. Gallie, honorary treasurer; and Drs. Owen Fowler and G. N. Hanbury, honorary secretaries. Of 172 divisional surgeons in the metropolitan area, 154 are now members, and its finances are in a very satisfactory position.

SPLENECTOMY FOR RUPTURE OF SPLEEN.

Two operations of this kind, of deep interest to the general surgeon, have recently been reported at a meeting of the Société de Chirurgie de Paris.¹ In the first case Caplesco of Bucharest removed the left kidney as well. A boy aged 14 fell about 20 feet, his abdomen striking against the ground. There was no external wound, but the parietal muscles on the left side were rigid, and there was a lumbar swelling which increased, with hæmaturia and symptoms of internal hæmorrhage. Rupture of the left kidney was diagnosed, and Caplesco cut down on it from in front at once, after removing much blood from behind the peritoneum. The hilum was partly torn through, and there were several lacerations on both surfaces of the kidney which was removed. Then the spleen was found badly lacerated at its hilum, and was therefore also extirpated. As there was oozing hard to control, a sterilized gauze tampon was placed in the loin. Caplesco then sutured the posterior parietal peritoneum over the tampon, and closed the abdominal wound, a strange manoeuvre, much criticized when the case was discussed. For two days there was much fever, and Caplesco at length removed the tampon through a lumbar incision, which was drained for a few days. The patient recovered. Souligoux, Morestin, Tuffier, and Auvray favoured more conservative methods. The first-named surgeon stated that on two occasions he saved a lacerated spleen, and the patient as well, by suture of the damaged organ, and Auvray believed in conservatism even for lacerated spleens; as for the kidney, it bore very bad wounds very well. He admitted, however, that it was only in exceptional cases that a laceration of the spleen could be sutured, a conclusion justified by the study of statistical reports of splenectomy for traumatism. The British surgeon would, we suspect, support M. Caplesco as far as the removal of the spleen was concerned, and would probably think that altogether he took the safer course when he removed the much-damaged kidney. The sinking of the tampon was hardly defensible, but the operator was, it appears, not present to reply and explain matters. M. Baudet read notes of another successful splenectomy. A man, aged 23, fell from a parapet over 35 ft., the left side of the thorax striking a pile of stakes. There was much shock, yet the patient came to quickly, and complained of nothing except smart pain in the left loin. When he was admitted into hospital muscular rigidity in the

left hypochondrium was marked, and several characteristic attacks of syncope occurred. Baudet operated thirty-two hours after the accident. He found the spleen torn completely in half, and removed it. The patient recovered. Mauclore, in discussing this case, remarked that in lacerations without detachment of a portion of the spleen suture may be sufficient, yet he doubted if it were ever quite safe. When the laceration completely separated a part of the spleen, removal of the organ was the only justifiable course. Probably a general surgeon who is a bold operator, but not experienced in plastic abdominal operations, does wisest if he remove a badly lacerated spleen.

CONDITIONS OF PRACTICE IN AUSTRALIA.

WE commented recently on a letter received from a correspondent in New Zealand, which shed light on the system of sweating medical men which obtains in that country, and we have now received from Mr. Booth-Clarkson, of Ayr, Queensland, a copy of the *Australasian Medical Gazette*, containing an article from his pen on The Prospects of the British Medical Profession, and Suggestions for Improvements. Mr. Booth-Clarkson rehearses most of the injustices and grievances under which we in this country suffer, and takes a somewhat pessimistic view of the position as a whole, especially with regard to overcrowding, inadequate fees and the difficulty of recovering them, and the absence of "reciprocity with other countries." We fully sympathize with his plea for continued effort and more thorough organization throughout the empire. But much of Mr. Booth-Clarkson's pessimism is explained by a cutting which he encloses from the *Townsville Daily Bulletin*. This is a report of a monthly meeting of the "Townsville Friendly Societies' Medical Union." In the absence of any intimate knowledge of the local conditions, the questions in debate seem obscure, and it is difficult to follow the tenour of the proceedings. We note, however, that the majority of the speeches were characterized by that cynical disregard for the reasonable interests of medical men which is still unfortunately the rule in assemblies of this class in all countries. One fact, however, emerged clearly—namely, that Mr. Booth-Clarkson had severed his connexion with one of the affiliated clubs, and it was said had even gone so far as to hint that in future he would not attend the members without charging his customary fees. This difficulty was got over by the simple process of transferring his late patients to the other Townsville doctors' lists, and a resolution was passed to the effect that the members of the lodge in question "be advised that they should get 'on the doctors' lists through the medium of sister 'lodges.'" A subsequent speaker indicated the source of the trouble in saying that "Dr. Booth-Clarkson 'desired to have the right to say who he would 'admit to the Ayr lodges,' and added that 'they 'would not stand that at Townsville.'" We seem to scent in this remark the old difficulty of the wage-limit. But it is interesting to note that one speaker warned the meeting that "the medical profession had 'a strong union in the British Medical Association, and the medical board might be taking on a big 'fight for the sake of a handful of members.'"

THE MEDICAL PROFESSION IN GERMANY IN 1908. DR. F. PRINZING gives some interesting information with regard to the number of the members of the medical profession in Germany in 1908 as compared with former years.¹ The total number in 1908 was 31,640, while the total population was about

¹ *Revue de Chirurgie*, January 10th, 1909, pp. 181 and 185.

¹ *Dent. med. Week.*, December 31st, 1908.

63 millions. This gives 5.02 medical men to every 10,000 inhabitants. In 1901 the proportion was 4.92 per 10,000, while in 1905 the highest figure was reached, namely, 5.08. In Greater Berlin, with a population of over 3 millions, there were 12.3 practitioners to every 10,000; in the other large towns there were 9.2, while in the rest of Germany there were only 3.8 per 10,000. The increase was most marked in Greater Berlin during the preceding three years, while it was definite in Wiesbaden, Dresden, and Essen. In Kiel, Halle, Königsberg, Hanover, Stuttgart, Cassel, Dortmund, Chemnitz, and Duisburg there was a distinct falling-off, and in certain country districts there was an actual shortage of medical practitioners. Thus on November 1st, 1908, some 356 districts were without a medical man. Of the total number of medical practitioners, only 55 are ladies; Berlin has 17, Breslau 5, Frankfurt-on-Main 4, Munich 3, and Hamburg and Dresden 2 each. In 1908, of the practitioners in the large towns 34.6 per cent. followed some form of speciality. This does not mean that the individual was not practising as a general practitioner as well; and, indeed, Dr. Prinzing believes that the majority of the German specialists do general practice. It must be remembered that in Germany the specialist announces his speciality by affixing on his name-plate a description, such as "specialist for diseases of women." In all there were 4,375 specialists in Germany in 1908, which is an increase of 371 on 1906. The most striking feature of this account to the English medical man must be the comparatively small numbers. With a total population of England and Wales of approaching 35½ millions, there are more than 7 medical practitioners per 10,000, as compared with 5 in Germany. The number of lady practitioners, too, is very considerably larger here than in Germany, the percentage of women practitioners on the German register being 0.17, while 1.88 per cent. of the names on our *Register* are those of women.

A GENERAL meeting of laryngologists was held at the Royal Society of Medicine on March 5th to organize a testimonial to Sir Felix Semon on the occasion of his retirement, which takes place at the end of the coming June. Mr. Butlin was unanimously elected Chairman of the General Committee and Dr. Dundas Grant, President of the Laryngological Section, was elected Chairman of the Executive Committee, which consists of the following: Mr. Butlin (Chairman, General Committee), Dr. Dundas Grant (Chairman of the Executive Committee), Mr. Charters Symonds, Mr. Cresswell Baber, Dr. J. B. Ball, Dr. Law, Dr. McBride, Mr. Herbert Tilley, Mr. E. Waggett, Dr. Sandford, Dr. de Havilland Hall, Dr. Seanes Spicer, Dr. StClair Thomson (Honorary Treasurer, 28, Queen Anne Street), Dr. Watson Williams (Honorary Secretary, 4, Clifton Park, Bristol), Dr. H. J. Davis (Honorary Secretary, 8, Portman Street, London, W.). Subscriptions may be forwarded to the Honorary Treasurer.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Old Age Pensioners and Medical Relief.—Sir Walter Foster asked the President of the Local Government Board on Wednesday if his attention had been called to an inquest on an old age pensioner named Blackwell, at Warwick, who died from pleuropneumonia without having had any medical attendance because she feared that the attendance of the parish doctor would jeopardize her pension; and if he could take any steps to let old age pensioners understand that they might receive medical

advice and attendance from Poor Law medical officers without running any risk of losing their pensions. Mr. John Burns said that his attention had been called to this case. Medical or surgical assistance (including food or comforts) supplied by or on the recommendation of a medical officer did not disqualify a person for receiving an old age pension or for continuing to receive one which had been already granted. He had issued a memorandum for the information of persons desiring to make claims for pensions, in which it was stated that such assistance as was mentioned above would not disqualify a claimant. Probably his right hon. friend's question and this reply would answer the purpose which he had in view of giving publicity to the law on this subject.

Medical Attendance on Postmen.—Mr. French called attention on Tuesday to the case of a postman who was taken suddenly ill and had to call in medical assistance, for which the postal authorities refused to pay, and asked whether it was not the rule that when there was no doctor connected with a post office the authorities did not make themselves responsible for medical attendance. Mr. Buxton said, in reply, that the bills of private doctors called in by Post Office servants were not paid except in case of injuries sustained on duty. There was no rule in the postmen's rule book in the sense supposed. In view of the distance of Mr. Wallace's residence from the nearest Post Office doctor, he had been removed from that officer's charge, and was now being paid the usual allowance of 8s. 6d. per annum in lieu of free medical attendance.

Tuberculosis.—Mr. Hudson asked the President of the Local Government Board if it was his intention during the present session to promote legislation for the eradication of tuberculosis, human as well as bovine, on national and compulsory lines, or whether it was his intention to do so deal with this matter at a later period during this present Parliament. Mr. Burns replied that legislation on the subject of bovine tuberculosis was at present receiving his attention in connexion with the Milk Bill which he proposed to introduce. As regards human tuberculosis he did not at the moment contemplate legislation on the subject. He had recently issued an order providing for the compulsory notification of pulmonary tuberculosis when occurring amongst persons in Poor Law institutions or under the care of Poor Law medical officers, and this order has, he was glad to find, stimulated voluntary notification of the disease when occurring among other persons in the large number of districts where a system for that purpose was in force. He should by no means lose sight of the matter, but he thought that developments with regard to it must be gradual.

Cleanliness in Dairies and Cowsheds.—Captain Morrison Bell asked, on Tuesday, what were the regulations as to cleanliness and management of dairies from which imports of fresh milk and cream came; and Mr. John Burns replied that the information in his possession was not sufficient to enable him to say definitely what were the conditions as to cleanliness and management in the dairies and cowsheds abroad, or as to the extent to which foreign regulations were enforced in these places. He had caused inquiries, however, to be made last year regarding the methods adopted at the single creamery in France from which all the fresh milk imported into this country appeared to be obtained, and from which also a considerable quantity of cream was imported. The result was generally satisfactory, as was also the result of the examination of some samples taken in London. He had the subject in mind in connexion with the Milk Bill, and he regretted that on these matters the jurisdiction of the Local Government Board was only applicable to the United Kingdom. In connexion with this subject it was stated by the President of the Board of Trade that 156 cwt. of fresh milk, of a declared value of £68, were imported into the United Kingdom in 1907, and 953 cwt., of a declared value of £437, in 1908; 4,231 cwt. of cream, of a declared value of £16,920, were imported in 1907, and 6,862 cwt., of a declared value of £26,556, in 1908.

Influenza in the Commons.—Last week Mr. Pirie asked the First Commissioner of Works if he was aware that over forty members of the Commons were laid up by influenza, and if he would consider the adoption of a more natural system of ventilation for the House. Mr. Harcourt replied that he much regretted the melancholy state of affairs complained of, but he was sorry to find that the proportion of 6 per cent. of influenza was not uncommon in other buildings and professions which were subject to the most natural systems of ventilation. In answer to other questions as to an inquiry into the ventilation, he said that the inquiry had been held; a large number of recommendations had been made, all of which he had carried out.

Lead Poisoning.—In answer to a question as to the statistics of lead poisoning, Mr. Gladstone said that the total number of cases of lead poisoning reported during the four years ended December 31st last under the Factory and Workshop Act was 2,448, of which 114 were fatal. The number of these cases showing symptoms of paralysis was 548; of encephalopathy, 84. The number of persons disabled could not be stated. There were other sources of lead poisoning outside the scope of the Factory Act, of which the most important was house painting and plumbing. Five hundred and fifty-seven cases (including 147 deaths) were reported as occurring in these two industries during the same period, but these reports were made voluntarily, and the figures could not be taken as complete. As regards experiments showing that lead is more often inhaled than swallowed, the only experiments of the kind of which he was aware were some that were now being carried out for the Lead Committee in connexion with the pottery industry. These had special reference to the question of the channel of absorption, but were not yet completed. They had not, of course, had anything to do with the revision during the last two or three years of various codes of special rules for different industries in which lead was used; but these rules contained precautions which were effective against both channels of infection. There had been no single "decision" to revise these codes. It had been the general policy of the Department to bring the older rules, as occasion arose, up to a modern standard.

Small-pox at Bristol.—On Tuesday Mr. Burns stated, in reply to a question as to how many cases of small-pox occurred in vaccinated persons before any unvaccinated person was notified as having the disease, that there were 11 such cases. It should, however, be stated that 24 cases of the 31 of which at present he had received particulars took place amongst persons over 20 years of age; that 22 out of these 24 persons had not been revaccinated since infancy, whilst the remaining 2 had already contracted the infection of small-pox before they were revaccinated. No case occurred amongst vaccinated children under the age of 10, but there were 2 amongst children who had not been vaccinated.

Accidents to Railway Servants.—In answer to Mr. Ellis, the following tabular statement was given on Monday last by Mr. Tennant:

Table showing the Number of Persons Employed by Railway Companies on December 31st, 1907, as Goods Guards and Brakemen, Permanent-way Men, or Platelayers and Shunters, the Numbers Killed or Injured in Accidents to Trains or by the Movement of Railway Vehicles in the Years 1907 and 1908, and the Proportion per 1,000 of the Killed and Injured to the Number Employed:

Occupation.	Number Employed (1907).	Killed.		Injured.	
		Numbers.		Numbers.	
		per Thousand Employed.	per Thousand Employed.	per Thousand Employed.	per Thousand Employed.
		1907.	1908.	1907.	1908.
Goods guards and brakemen	16,786	41	29	2.44	1.73
Permanent-way men or platelayers	67,184	89	76	1.32	1.13
Shunters	13,158	39	34	2.97	2.58
				1,035	955
				62	57
				2.6	2.36
				76	69

From causes other than accidents to trains or the movement of railway vehicles, the numbers killed or injured were:

Occupation.	Killed.		Injured.	
	1907.	1908.	1907.	1908.
Goods guards and brakemen	—	—	438	513
Permanent-way men or platelayers	6	—	2,132	2,256
Shunters	1	—	220	276

Simple Continued Fever at Malta.—In answer to Mr. Lupton, on Monday last, Mr. Haldane stated that the number of cases of simple continued fever were 323 in 1907, and 303 in 1908; there were 1,275 cases in 1897 and 1,509 in 1898. The figures for the average strength of the troops at Malta for the same years were: 1897, 8,023; 1898, 7,300; 1907, 5,700; 1908, 6,030.

The Peabody Buildings, St. Luke's, and Vaccination.—In answer to Mr. Lupton, who asked the President of the Local Government Board if he had inquired into the action of the Peabody officials as regards vaccination exemptions, Mr. Burns stated on Tuesday that he had made inquiry on this subject, and he was informed that in any case in which it came to the knowledge of one of the superintendents of the Peabody Dwellings that a tenant refused to have his child vaccinated, notice to quit was served. He had no control over the trustees of the dwellings in this matter, but he found from the vaccination officer that in no instance had he shown the declaration exempting from vaccination to their agents or superintendents.

Food Wrappers.—Mr. Courthope asked the President of the Local Government Board on Tuesday whether he had power to regulate the packages, bags, and wrappers in which food was sold, and whether he would consider the advisability of prohibiting the use of old newspapers for wrapping meat and other articles of food. Mr. Burns answered that The Public Health (Regulations as to Food) Act, 1907, enabled the Local Government Board to make regulations authorizing measures to be taken for the prevention of danger arising to public health from the distribution of articles of food intended for sale for human consumption, but he had no information which on grounds of public health would justify regulations of the kind suggested in the last part of the question.

Lady Inspectors for Boarded-out Children.—Last week, in answer to Sir Walter Foster, the President of the Local Government Board said that the appointment of lady inspectors for children boarded out within the unions was under consideration, but that he had not at present arrived at a decision with regard to it.

The Dairies, Cowsheds, and Milkshops Order.—Mr. Burns stated last week that the number of boroughs and other districts in which regulations under this order were not in force was as follows: Boroughs, 14 out of 327; other urban districts, 71 out of 814; rural districts, 78 out of 666.

India.

[FROM A CORRESPONDENT.]

THE BOMBAY MEDICAL CONGRESS.

THE medical profession in India owes much to His Excellency Sir George Clarke for his initiation of a scheme early last year for the holding of a Medical Congress in Bombay. It has not only brought together a large number of the best class of workers in tropical medicine for purposes of mutual instruction, but it has also helped forward the whole medical profession in the peninsula. It has demonstrated to the world the vast amount of good work which has been done, and is being done, by the members of the medical services, and has shown also that the general body of the profession in India is anxious to avail itself of all opportunities for professional advancement, and is ready for that official recognition and status which it obtains in all civilized countries. It is to be hoped that the Medical Congress will be the means of pushing on the consideration of most important questions connected with the medical profession in India which have recently become the subject of legitimate agitation and discussion—namely, a proper Medical Registration Act, a Druggists Act, regulations for the suppression of bogus qualifications, and a scheme for the registration and organization of qualified nurses.

The Congress has aroused great public interest, as has been shown by the care with which the local press has followed the deliberations from day to day; and now that the interest of the Government and the public have been aroused in medical work, and the value of research has been recognized, it is to be expected that the hope expressed on all sides that the Congress may meet again in three or four years will be fulfilled.

The exhibition attached to the Congress has had a valuable educational effect; it has demonstrated the excellence of the products of those firms connected with medical work, many of them entirely Indian in their operations and administration, whose exhibits of surgical instruments and aseptic furniture, drugs and foods, and sanitary appliances and models have been carefully examined by crowds of educated native visitors.

The Congress was opened on February 22nd in the University Convocation Hall by His Excellency Sir George Clarke in the presence of a large gathering, who followed the Governor's interesting and sympathetic remarks with close attention. After tracing the most important achievements of the medical profession during the last few decades, step by step, His Excellency concluded with the following practical exordium: "The Congress, as Surgeon-General Stevenson tells us, has thrown its net far and wide. I earnestly trust that the papers read and the interchange of views thus arising will give a fresh impetus to medical progress in India. Germs of thought will surely be evolved, which will blossom into achievement. Our students may feel inspired to high aims, and will at least realize that their college training is only an introduction to the study of modern medical science. I am hopeful that the vernacular papers, many of which have helped to disseminate facts about the plague serum, will assist us in spreading knowledge of a general character, in which India is sadly deficient. Lastly, I am sure that this Congress will emphasize the essential solidarity of the noble profession of healing, which knows no distinction of race or colour, and unites all true workers as members of one great brotherhood engaged in combating suffering and disease throughout the world."

Section I.—Cholera, Dysentery, Enteric Fever, and Tropical Diarrhoeas.

Major Leonard Rogers, I.M.S., read a paper on cholera, with special reference to its treatment. The main point advocated was the use of intraperitoneal injections of hypertonic saline solutions, at the same time taking care to maintain the blood pressure. The author showed a special cannula he had devised for the purpose, which had been used with good results. Khan Bahadur N. Choksy followed with a paper detailing the general lines of treatment adopted in a series of 533 cases, in which rectal

injections of saline solution were used. A discussion followed.

Dr. Nicholls, of the U.S. Army Medical Corps, described experiments undertaken in the Philippines on coloured underclothing for soldiers exposed to the tropical heat.

Captain F. H. Hutchinson, I.M.S., described the method of preparing and storing calf vaccine in the Belgaum dépôt, and the difficulties connected with this storing during the warm seasons of the year. He discussed the relative value of glycerinated and chloroform-glycerinated vaccine, and on the whole gave his preference to the former.

On the second day papers on dysentery in Indian galls were contributed by Lieutenant-Colonel W. J. Buchanan, I.M.S., and Captain W. Forster, I.M.S., who has recently been deputed by the Government of India to study the subject. Captain Gordon Tucker, I.M.S., read a paper on appendicostomy in the treatment of intractable ulceration of the colon, giving notes of five cases of chronic dysentery in which this operation has been done, and indicating the type of Indian dysentery in which it was invaluable.

On the last day there was a discussion on enteric fever, including an interesting paper from Lieutenant Colonel Semple, R.A.M.C., on cases of recovery from typhoid acting as prolonged carriers of the infecting bacilli. Dr. Van Loghen read a paper on the experience of typhoid fever in Sumatra, sent by Dr. Schuffner.

Section II.—Malarial Fever, Plague, Etc.

In this section, presided over by Surgeon-General Hamilton, C.B., I.M.S., Professor Ronald Ross, C.B., F.R.S., in starting the discussion on malaria by a paper on the practice of malaria prevention, emphasized the economic effects of malaria on the community; he described the methods by which the amount of malaria in Mauritius was investigated, and laid down the following rules for sanitary officers in checking malaria:

1. All antimalarial measures are good and useful, and each should be employed in its proper place.
2. For stations where the population is great and dense, mosquito reduction should be the aim.
3. For scattered populations and villages the general distribution of quinine should be employed.
4. In the presence of severe malaria both mosquito reduction and parasite reduction should be employed together.
5. The sanitary officer should begin with those measures which can be immediately adopted, that is to say, as a general rule, with the cheapest ones.

Attention was directed to the necessity of parasite reduction in native children who were the principal homes for the malarial parasites.

The paper on the human factor in the spread of malaria, by Captain S. R. Christophers, I.M.S., and Mr. C. Bentley, dealt with a matter which has often been lost sight of in India; its consideration helps to explain the recent very serious epidemic of malaria in Bombay, where there has lately been an enormous congregation of labourers from all parts of the Presidency, on account of the great dock extensions which are in progress, and of the great impetus given to building in the island during the last four years. The same gentlemen also read a paper on the intimate pathology of malaria in relation to blackwater fever.

On the second day a discussion on plague was opened by a paper by Professor Kitasato, read by Professor Shiga, which showed that the Japanese investigators had arrived at the same conclusion as had been come to in India. Major Lamb described the facts connected with the etiology of plague, and Captain Liston indicated the lines on which plague epidemics should be dealt with. Essential measures were the removal of conditions favouring rat infestation, the prevention of importation into non-infected places, and, when these have failed, inoculation. In the "non-essential and doubtfully efficacious" measures he included isolation and treatment of the sick in hospitals, disinfection, and evacuation of plague-infected houses. The conclusions arrived at by Captain Liston were hotly contested. Unfortunately some of the speakers wandered from the subject in order to discuss the alleged shortcomings of the Bombay Municipality.

Major S. Browning-Smith, I.M.S., read an interesting paper on the recrudescence of plague in localities where no second infection could be traced, and gave the results of his extensive experience in the Punjab.

*Section III.—Animal Parasites and Disease Carriers,**Leprosy, etc.*

In this section Captain E. D. Grieg, I.M.S., gave a description of the work of the Sleeping Sickness Commission, and enumerated the facts connected with tsetse flies ascertained to date. The operations directed against the fly were, he said, on the lines of (1) destruction of the pupa of the fly, by the clearing of undergrowth; the destruction of the foodstuff of the fly, including an investigation into the suggestion that had been made that the blood of the crocodile was the main food supply of the fly. (2) The possible destruction of the fly by other animals which might prey on it. Papers were also read on the dissemination of disease by ticks and diptera, by Captain Carter, I.M.S.; on non-biting flies as carriers of disease, by Dr. J. T. Nash; and on Indian sand-flies, by Mr. Howlett, the Government Entomologist.

On the second day a paper on snake venom contributed by Sir Lauder Brunton was read, and Lieutenant-Colonel Buchanan showed some cases of lathyrism.

On the third day beri-beri and leprosy were discussed. The nascent treatment of leprosy appears to have given several workers, including Captain Beauchamp Williams, of Beshire, encouraging results.

Section IV.—Sewage Disposal, Water Supplies, Disinfection, etc.

This section, which met under the presidency of Lieutenant-Colonel Crimmin, V.C., C.I.E., I.M.S., discussed questions of water supply and purity of water. A paper on India, the Haj, and the International Sanitary Conventions, by Dr. F. C. Clemow, was read, and another paper on unhygienic Bombay by Drs. Cursetjee and Master, was a prolific subject for discussion.

Section V.—Surgery in the Tropics.

The meetings of this section attracted a full and interested audience. The principal subjects were cataract and vesical calculus. The extraordinary amount of clinical work done by officers of the Indian Medical Service was well illustrated by Major Smith, of Jullundur, speaking from experience of twenty thousand cataract extractions, and Surgeon-General Stevenson, from over five hundred litholapaxies per annum during a long series of years in Hyderabad, Scinde. Major Ashton Street, F.R.C.S., I.M.S., read a paper on the treatment of elephantiasis by artificial lymphatics, a method which is likely to help considerably in the treatment of a most troublesome group of cases. Captain T. S. Novis recorded his experience of the operation of epilepsy, which is also likely to be of great use in the treatment of malarial cirrhosis of the liver. Dr. E. F. Neve gave an interesting account of the etiology of one variety of epithelioma in Cashmir, due to chronic burns.

The Transactions.

It would be impossible to condense the many valuable papers presented to the notice of the various sections. They represent the very latest additions to knowledge in the many branches of tropical medicine and surgery. The *Transactions* of the Congress will form a very valuable book of reference to all interested in these subjects. The publication of this volume, which will contain from 300 to 400 pages, has been placed in the capable hands of the *Times of India* Press. Probably it would have been better if the papers to be read had been extended over five days. At any rate the medical profession in India has learnt much from this meeting, which reflects the greatest credit on the organizing powers of the General Secretary, Lieutenant-Colonel W. E. Jennings, I.M.S.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

JUBILEE OF THE SICK CHILDREN'S HOSPITAL, EDINBURGH. This is the jubilee year of the Sick Children's Hospital in Edinburgh, and at a meeting of contributors, held in Edinburgh on March 17th, reference was made to the gradual development of the institution, which, as the Chairman said, since its foundation in 1859, had been one of unchecked progress. A beginning was made in 1859, when

a house was purchased in Lauriston, which accommodated twenty children; this was extended in 1860, and the Lauriston Hospital was opened in 1863. The present hospital, which is one of the best-equipped in the kingdom, was opened in 1895 at a cost of £52,000.

Dr. Allan Jamieson, President of the Royal College of Physicians, in the course of a short speech, said that it was common knowledge that the rise of hospitals owed its inception to Christianity, but it might not be widely known that hospitals in their sense of the word took origin in the Holy City of Jerusalem itself. Dr. Jamieson also referred to the educative power of hospitals, and particularly of children's hospitals. Many of the patients were drawn from poor and often squalid homes. Then admission to hospital was for many the first glimpse they ever had of what true comfort was. Too many had not previously known what it was to have a clean bed to themselves; to have fresh, pure air; to be tended by gentle, loving hands; to be served with well-cooked, appetizing food, and to hear round them only kind, affectionate language. To many the change was almost magical, and at their receptive age the effects of their experience in the hospital was by no means so transient as it might seem. Hospitals, therefore, should not be regarded as merely institutions where the cure or alleviation of suffering was aimed at, but as very valuable moral, mental, and religious educators, and should consequently receive liberal support on these grounds alone.

STATE REGISTRATION OF NURSES.

A meeting in connexion with the promotion of the Registration of Nurses (Scotland) Bill was held in Glasgow on March 17th. Dr. Mackintosh reported that the committee formed at the end of last year to go carefully into the clauses of the English bill felt that a Registration Council, with head quarters in London, with practically no representation from Scotland, should be resisted in the interests of Scottish nurses, and they were unanimously of opinion that a separate Registration Council should be appointed for Scotland. After considerable discussion, it was formally agreed that the association should be known as the Association for the Promotion of the Registration of Nurses in Scotland. Lord Inverclyde was appointed president, Dr. Mackintosh honorary secretary, and Dr. Johnston honorary treasurer.

A ZOOLOGICAL SOCIETY.

A meeting of persons interested in the formation of a zoological society for Scotland was held in Edinburgh on March 18th. It was formally agreed to found a society, to be known as the Zoological Society of Scotland, for the purpose of establishing, in the first instance, a zoological garden in or near Edinburgh. A committee was appointed.

THE ONTARIO-CHIRURGICAL SOCIETY OF SCOTLAND.

The annual general meeting of this society was held on March 12th, at 3.30 p.m., Mr. C. F. Sutcliffe, L.D.S., President, in the chair. The Honorary Treasurer's annual statement showed that the financial condition of the society continued satisfactory, and that the membership continued to increase. The Curator-Librarian intimated the donation of various books to the library and of specimens to the museum, and described the manner in which the society's rooms had been redecorated and fitted up for the convenience of members. The following office-bearers were appointed for the session 1909-10:

President: J. Morris Stewart, L.D.S.
Vice-Presidents: J. Douglas Logan, L.D.S.; Peter Cumming, L.D.S.
Honorary Treasurer: L. Storrow Shennan, L.D.S., D.D.S.
Curator-Librarian: A. W. Greig, L.D.S.
Editor of Transactions: A. Shennan, M.A., L.D.S.
Honorary Secretary: R. Lindsay, L.D.S.
Council: C. F. Sutcliffe, L.D.S.; W. T. Finlayson, L.R.C.P. and S.E., L.D.S.; T. E. Johnston, L.D.S.; R. S. Sanderson, L.D.S.

Dr. Theodore Shennan read an interesting paper entitled, *Looking Backward in Dentistry*, in which he traced the history of dental practice from the earliest times, and showed that not a few of the more modern developments of dental work, such, for example, as the crowning of roots and teeth with gold, had been anticipated by those early practitioners. By means of a series of lantern

slides Dr. Shennan showed various forms of early dental instruments, and also exhibited several actual specimens.

The annual dinner of the society took place in the evening in the Caledonian Station Hotel. Mr. J. Morris Stewart, the newly-elected President, occupied the chair, and Mr. J. Douglas Logan acted as croupier. Among the society's guests were Dr. Theodore Shennan, Dr. W. Allan Jamieson, President of the Royal College of Physicians of Edinburgh; Dr. R. McKenzie Johnston, Secretary and Treasurer of the Royal College of Surgeons of Edinburgh; Dr. Rainy, Secretary of the Royal College of Physicians; and Mr. G. M. Stuart, Secretary of the Edinburgh Dental Hospital and School. The company included members of the society from different parts of Scotland, and a most enjoyable evening was spent.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

ROYAL VICTORIA HOSPITAL, BELFAST.

At the meeting of the board of management on March 17th the Vice-Chancellor of the Belfast University drew attention to the retirement, under their by-laws, of their chairman, honorary treasurer, and honorary secretary, and proposed a resolution embodying the deep regret of the board, and their high appreciation of the labours of those gentlemen. This was seconded by the Dean of Belfast, and warmly supported on behalf of the medical and surgical staff by Sir John Byers, who said that Sir William Crawford, the chairman, had taken the keenest interest in the creation of the new hospital, and laboured indefatigably in its behalf in its early years. He was thrown much in contact with the medical and surgical staff, and by none more than by them was his retirement regretted. He always showed warm sympathy and intelligent appreciation of their endeavours, and any project of theirs was sure of a reception marked by high courtesy and kindness.

STUDENTS' ANNUAL DINNER, QUEEN'S UNIVERSITY, BELFAST.

The students' annual dinner was held in the Great Hall of the College on St. Patrick's Day. The Chancellor of the University (the Earl of Shaftesbury), who was in the chair, was supported by the Vice-Chancellor (the Rev. Dr. Hamilton), and many of the professors, members, and friends of the college to the number of over a hundred sat down. As this was the first occasion on which the dinner was held under the auspices of a university, the speaking was both retrospective and prospective, and the prophecies of success were bright and cheering.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

MANCHESTER AND DISTRICT.

MANCHESTER ASSOCIATION OF REGISTERED MEDICAL WOMEN.

On March 18th Mrs. Garrett Anderson, M.D., Mayor of Aldeburgh, was entertained at breakfast at the Midland Hotel by the Manchester Association of Registered Medical Women. Dr. Merry Smith, Chairman of the Association, in a few words of welcome, expressed her sense of the honour of having as guest one who in the past had overcome so many difficulties, and made the study of medicine so much easier for the women of to-day.

Mrs. Garrett Anderson, in reply, expressed her pleasure in meeting so many Manchester medical women, and said that medical women's societies fulfilled a distinct purpose which could not be met by existing men's societies. They permitted a freedom of social intercourse and interchange of ideas which was otherwise impossible. The secret of success was in part brain power, but much more was it due to personal character and loyalty to fellow-workers, combined with capacity for hard work.

THE MANCHESTER SURGICAL AID SOCIETY.

Judging by the statement just issued by the Chairman and Treasurer of the Manchester Surgical Aid Society,

this is one of those societies, by no means too common among medical charities, which is doing good work without encouraging improvidence. It was founded eleven years ago to supply artificial limbs, trusses, etc., to the suffering poor; in 1898 only 53 cases were assisted, while in 1908 the number was 314. Applicants are referred to the society by district nurses and medical men, especially those connected with hospitals, as none of the hospitals of the district supply free surgical appliances. Every recommendation is signed by a medical man, and the circumstances of the applicants are then investigated by the District Provident Society, and, wherever possible, patients are required to pay something towards the cost. The management expenses are under £50, and have tended to decrease somewhat in late years. The total subscriptions and donations last year were only £142, and there was a deficit on the year's working of £70, which, with a previous deficit, has caused a bank overdraft of £100. During the first five months of the current financial year the applicants were 70 in excess of the corresponding period of 1907-8, and, unless the work is to be much curtailed, the society must receive additional support. This is one of those charities that medical men can support without feeling that they are encouraging improvidence, and its work does not seem to be sufficiently well known to the profession in Manchester.

INEBRIATE HOMES.

Some time ago attention was called to the opinion expressed by the Manchester justices that the successful cures of inebriety by detention in inebriate homes were so few that the homes were hardly worth the great cost. This opinion led to considerable correspondence in the Manchester newspapers, and supporters of such homes gave their experience that the cures were far more numerous than were ever made public. Nevertheless, the justices defended their opinion, giving statistics in support. We now have a further defence of the Lancashire Inebriate Reformatory in the annual report of the medical inspector, Dr. Gill. It is said in the report that a fair proportion of successes can actually be pointed to, but Dr. Gill has to complain that there is often too great delay in committing inebriates to a home. They are allowed to degenerate till they have become prematurely senile and feeble and so almost irreformable. It would be far better that all inebriates, reformable or otherwise, should be segregated on account of their evil influence on the young, and in the interests of decency and good order among the majority. Habitual drunkards often become such from their environment and from association with other chronic drinkers. Dr. Gill holds that habitual drunken mothers should be removed from their children, and that it is unfortunate that inebriates are ever allowed to become parents. To commit irreformable inebriates to prison is an injustice, as they are only to a limited extent responsible for their offences. At the same time it is pointed out that reformatory treatment is cheaper than either prison, asylum, or workhouse. Therefore, it is maintained that on the threefold ground of economy, the interests of the present generation and the future welfare of the race, inebriates ought to be segregated. This line of argument was hardly considered by the justices several months ago, as they looked rather to the immediate effects on the patients themselves.

NEWCASTLE-UPON-TYNE.

NORTHUMBERLAND AND DURHAM MEDICAL SOCIETY.

Address by Sir Lauder Brunton.

On March 18th Sir Lauder Brunton delivered an address on the treatment of heart disease before the Northumberland and Durham Medical Society. Dr. Peart, of North Shields, president of the society, occupied the chair. The address, which was delivered to a large audience in the Library of the Royal Victoria Infirmary, was full of thought and suggestion, and those who heard it were unanimous as to its helpfulness to the physician and the general medical practitioner. On the motion of Dr. James Drummond, of South Shields, a hearty vote of thanks was given to Sir Lauder Brunton for his kindness in coming to Newcastle.

Banquet.

In the evening a banquet was held in the Royal Turk's Head Hotel. The President, Dr. Peart, was in the chair, and 113 sat down. The guest of the evening was Sir Lauder Brunton. After having honoured the toast of "The King," the President called upon Dr. Hume to propose the health of "Our Guest." It was most appropriate that Dr. Hume should have been invited to discharge this agreeable duty to his old fellow student and class-mate. Dr. Hume, becoming reminiscent, gave many interesting biographical details of Professors Goodsir, Bennett, Syme, and Sir James Simpson, and of the influence of the Edinburgh teaching of that period. It was in the Metropolis of the North and in the early years spent in St. Bartholomew's Hospital and its laboratories that the good work was done and the foundation laid of the reputation and subsequent distinction which Sir Lauder Brunton had achieved. In his reply Sir Lauder was not less happy than the proposer of the toast. Supplementing what Dr. Hume had said of Edinburgh days and their teachers, Sir Lauder Brunton went on to speak of the value of experimental research in medicine and of the relationship of physiological action and chemical constitution. The pioneers of this branch of the experimental methods were Professor Crum Brown and Sir Thomas Fraser, of Edinburgh. It was impossible to estimate the extent and the worth of the information which had been obtained by experiment. The activity of the antivivisection societies had called into existence the Research Defence Society, whose object it was to inform public opinion, to show that vivisection was not needless cruelty, and that any pain inflicted upon animals was a mere cypher compared with what was saved. The outcome of Sir Lauder Brunton's visit to Newcastle and his earnest pleading on behalf of the society will be to hasten the development of the branch of the Research Defence Society towards the creation of which steps had already been taken. To the Lord Mayor of Newcastle was entrusted the toast of "The Northumberland and Durham Medical Society." This was acknowledged by Dr. Peart, who is not only its president but the oldest member. Alluding to his long association with the society, extending over fifty-one years, Dr. Peart announced that in order to mark this circumstance and the two occasions on which he had been president he was prepared to offer a badge of office to the society for future presidents to wear. From the heartiness of the applause which followed the announcement there is not the least doubt that the gift will be gratefully accepted by the committee. Upon Dr. W. E. Hume was imposed the burden of the arrangements of the banquet. He is to be congratulated upon its success.

BIRMINGHAM.*BIRMINGHAM MEDICAL INSTITUTE.*

THE Birmingham Medical Institute has at present only 190 members. The list is very small when compared with the large number of practitioners within the radius of fifty miles of Birmingham who are eligible for election. The library contains 14,268 volumes; during the past year 146 volumes have been added, and of these 58 were gifts; 72 periodicals are supplied to the reading room. During the year 799 volumes were issued to 110 borrowers. The expenditure during 1908 was £505, and there was an excess of income over expenditure of £16. The sum of £100 has been bequeathed to the funds by the late Dr. Edwin Rickards, a former president of the institute.

WALES.*INSANITARY SHIPS.*

ACCORDING to the annual report of the Newport Port Sanitary Authority, 3,587 vessels arrived at the port last year. Of the 1,388 vessels entered from foreign ports, 226, or 16.2 per cent., had sanitary defects; of the 2,199 vessels entered from coastwise voyages, 307, or 13.9 per cent., were insanitary. The fact that 1 out of every 7 vessels arriving at Newport after short coast voyages from other British ports had sanitary defects showed the necessity for careful supervision. In previous reports Dr. Howard Jones has drawn attention to serious hygienic defects in

the accommodation provided on some new vessels, and now adds that the time has arrived when the whole question of the construction of crew spaces on modern hygienic principles should receive the thorough consideration of the Board of Trade. Inspector Roberts, in his report, refers to two part cargoes of tinned herrings in tomato sauce which arrived from New York. A considerable proportion of the tins were "blown." They came originally from a factory at another town, were consigned to a customer at New York, were rejected there as some were found to be "blown," and then conveyed to Newport. The cases were landed for inspection at the docks, and after being examined 8,436 tins out of 37,883 which formed the consignment were buried and the sound sent back to the factory.

THE MEDICAL OFFICER OF HEALTH FOR ABERDARE.

Many reasons have been put forward from time to time in favour of the abolition of the pernicious practice which prevails in the provinces of electing medical officers of health for short periods. One of the most convincing is the facility with which under it the electing authority can add to the duties of the officer each time he comes up for re-election. As a rule, these additions to his duties are such as he may legitimately undertake, providing that adequate remuneration is offered for their performance. The Local Government Board, however, always requires that no part of such additional remuneration shall come out of the county funds. About two years ago Dr. M. J. Rees was elected the first whole-time medical officer of health for the urban district of Aberdare, and when, in the ordinary course, he came up for re-election a few weeks ago, it was suggested that, in addition to his routine duties, he should periodically examine the milk supplied to the town, whether it came from local vendors or from other counties, and that he should make a periodical inspection of the cows that supplied the milk in the district. Dr. Rees very properly demurred to having thrust upon him these additional duties, and pointed out that the analysis of milk was a chemical and bacteriological process, which was, as a rule, carried out by the county analyst, while the examination of cows was the work of a veterinary surgeon. After some discussion, in the course of which one councillor inquired if it were possible to distinguish tuberculous milk by tasting, the question of reappointing Dr. Rees was referred back to the Health Committee in order that information might be obtained as to the precise duties which devolved upon him. As those duties have been very clearly defined by the Local Government Board in the Order of March 23rd, 1891, the committee should not have much difficulty in coming to a decision on the matter. In the event of difficulties presenting themselves, the question at issue is so simple and clear that it would readily be decided by reference to the Local Government Board, by whose decision we are quite certain Dr. Rees would loyally abide.

Special Correspondence.**VIENNA.***Jubilee of Eminent Surgeons.—Number of Medical Students.—Health of Vienna.*

A SHORT time ago two of the leading surgeons of Vienna celebrated their jubilee. One of these, Professor v. Frisch, a pioneer of kidney and bladder surgery, attained the age of 60 in full health, surrounded by numerous pupils, friends, and grateful patients. Professor Zuckerkandl, formerly one of his assistants, in a congratulatory address, pointed out the difficulties which at the outset had impeded modern surgery, and the pioneer work done by Professor v. Frisch. The other jubilee was that of Professor v. Eiselsberg, director of the second surgical clinic of Vienna, who celebrated the twenty-fifth anniversary of his graduation. He attained at a comparatively early age one of the highest positions which a surgeon can reach. After being a pupil at Billroth he went to Königsberg as professor of surgery, where he gained fame as scientist and surgeon. He was called to Vienna to succeed Albert. Here his clinic is the centre of modern surgery. A

Festschrift comprising all the important publications originating from Eiselsberg's clinics was presented to him by his pupils.

The decrease in the number of medical students is already making itself felt in medical circles. Not only are appointments in hospitals more easily and quickly obtained than even five years ago, but in many of the smaller hospitals salaries have to be paid to the physicians and surgeons to induce them to devote some of their time to the work there, whilst twenty years ago these posts were eagerly sought after by members of the profession. The increase of the population, the improvement of the material position, and the education of the general public has absorbed many doctors formerly doing nothing but walk the hospitals. The increase of the system of Krankencassen, or the compulsory contract practice, has also caused many practitioners to accept the post of club doctor for moderate pay, rather than to work in the hospital for nothing. On the other hand, the unsatisfactory condition of the ordinary practitioners, together with warnings issued by several medical corporations, have induced many students to turn their minds to other studies than medicine. If things do not change much in the next few years, the profession may, by sheer scarcity of doctors, attain a much better position than it now occupies.

The health of the capital has been remarkably good during the last winter months. In November, December, January, February, the weather was fairly equable, though cold. Thus the death-rate went down as low as 15 per 1,000, which is a record for this city during the forty years that regular reports of the health bureau have been published. Only lately, on account of some small epidemics of measles, scarlet fever, and influenza, the figures have gone up a little, but still they are below the average. The number of births has also decreased a little compared with the figures for the last five years, but this is quite insignificant compared with the saving of life due to the low death-rate. Hence the annual increase of the population by 2 per cent. will surely be more than maintained. Already Vienna has passed the second million of its inhabitants, and counts among the healthiest large cities, in spite of the phthisical cases which are believed to be so numerous here.

Correspondence.

DIAGNOSIS IN STOMACH SURGERY.

SIR,—I wish to support Dr. Hutchison's protest against the neglect of diagnosis by some of those who practise gastric surgery, but I would like to include in the complaint many practitioners who do not operate, but who are unable or unwilling to appreciate the value of careful preliminary diagnosis, and either hand a case straight over to a surgeon for an exploratory incision or persist in treating the case by medical means, in spite of continued failure, and the presence of symptoms which at least suggest the desirability of further investigation.

For example, a lady came some distance to see me on account of stomach trouble which had existed for twenty years. I found her stomach much dilated with visible peristaltic waves. I told her I thought there was sufficient reason to suspect pyloric obstruction, which would require an operation, but that before coming to this conclusion I should want to have an opportunity of making a further examination of the stomach. I wrote to her family doctor telling him this, and explaining the nature of the examination which I thought should be made. In reply, I got a letter to say that the lady was being sent to a physician in London, who, he hoped, would decide between us, as, in his opinion, she was suffering from nothing but functional disease. I wrote to the physician, enclosing a copy of my notes, but he decided that the lady should continue to undergo the medical treatment which had proved so ineffectual for so many years, and declined to sanction any further examination of the stomach. As this gentleman is considered an authority on stomach diseases, it is somewhat disappointing and shows that the difficulties in the way of intelligent management of stomach cases are great.

When a case of stomach disease has resisted ordinary medical treatment, I hold it to be our duty to proceed to

further examination, and this is so simple that there really is no excuse for neglecting it. A meal of any kind, perhaps the simpler the better, but which should certainly include twenty or thirty currants, as these are easily identified, is given; six hours afterwards, no other food or drink having been taken in the interval, the stomach should be washed out, and, if there are any remains of food, pyloric obstruction of some kind or another may be diagnosed, and the case should be handed over to a surgeon for gastro-enterostomy. These are the cases that by universal consent do best, and they are much more common than is generally supposed. There may be very serious pyloric obstruction without any dilatation of the stomach or any vomiting.

The other helpful means which may often indicate the desirability of an operation is by the examination of the faeces for latent blood. The best test is to add 10 drops of a saturated alcoholic solution of benzinid to a small portion of faeces in a test tube and then 20 or 30 drops of peroxide of hydrogen (20 vols.), if blood is present a persistent dark blue colour is developed.

I have used both these methods for a sufficiently long time and over such a large number of cases that I can recommend them with perfect confidence as not likely to mislead.

In addition to these, and such conditions as perforation, subphrenic abscess, impermeable oesophageal stricture, there is a residue of cases which do not get better in spite of medical treatment, and where neither of the above indications for surgical operations can be discovered, that is to say, there is no evidence of pyloric obstruction or of any bleeding ulcer, yet the patient suffers from recurrent attacks of pain and vomiting. I have under such circumstances sanctioned an operation as a *dernier resort*, and I shall probably do so again, although my experience has been that the operation does no good, and should not be recommended.—I am, etc.,

Birmingham, March 23rd.

ROBERT SAUNDY.

THE DIAGNOSTIC VALUE OF HUNGER PAIN.

SIR,—It has afforded me great pleasure to observe that Dr. Robert Hutchison is gravely concerned as to the diagnostic value of that symptom to which I have given the name "hunger pain." I feel sure that he wishes to elicit from me a reply to his letter in your issue of March 20th, since he specially quotes my view. I confess, therefore, that when writing the paragraph he reproduces from my paper, Dr. Hutchison was in my mind. I read, I think, everything which Dr. Hutchison writes upon the question of stomach derangements, and I am always convinced that the views he so ably expounds are fundamentally inaccurate. In all that he writes he seems to me to rely upon hypothesis and conjecture, when he should be guided by facts. In his letter he recounts the "natural history of duodenal ulcer" in various stages; the first, when recurring attacks of "hunger pain" are present, is, we are informed, one of "hyperchlorhydria"; the second is one of "continuous hypersecretion"; finally, he believes, "the formation of a duodenal ulcer is only the terminal event in a case of hypersthenic dyspepsia." I have operated upon a large number of patients who display the symptoms Dr. Hutchison describes, and I find that in the early as in the late stages a duodenal ulcer is present; in the early stages so small that it may sometimes be excised, in the latter stages so large that gastro-enterostomy is necessary. These patients have not always, or even usually, the variations in the quantity or in the condition of the gastric secretion which Dr. Hutchison holds to be the cause of their symptoms.

There are certain cases of "dyspepsia" in which attacks occur, attacks in which a definite group of symptoms, chief among them being "hunger pain," is present. The cause of these symptoms Dr. Hutchison believes to be an alteration in the quality or the quantity of the gastric juice; the condition, he holds, is one of "functional" disorder. As to the pathological conditions present in such cases, Dr. Hutchison offers no evidence. He does not see the stomach or duodenum, and he cannot therefore be a witness to their integrity. Whether an ulcer is present or not he has no means of telling. If an ulcer be present he cannot know where it lies. His pathological acquaintance

¹ See BRITISH MEDICAL JOURNAL, November 16th, 1907, for a description of "hunger pain."

with the condition does not exist. All is chemistry and make-believe. In patients who are referred to me with these symptoms I do not hesitate to diagnose duodenal ulcer, and I advise operative treatment. At the operation I am able to demonstrate the ulcer to an onlooker who before may have been sceptical. That, briefly put, is the difference between Dr. Hutchison and myself. We describe the same group of symptoms; he attributes these symptoms to a "functional" disorder; I have been able to demonstrate in over 230 cases that they are due to a structural lesion in the duodenum. And I know that duodenal ulcer can be diagnosed from the symptoms alone with a margin of error that is less than 5 per cent.

I state the position quite frankly, because it seems to me that it is hardly a matter to be settled by debate. There is need rather for patient and unprejudiced observation. If Dr. Hutchison will submit his cases to the surgeon, he will find a duodenal ulcer to be the cause of the symptoms I have described. If he is loth to do this, I shall be happy to give him the opportunity to see and examine my cases before operation, and at the time of operation I will accept his decision as to the existence and the position of any organic lesion. Dr. Hutchison does not tell us what knowledge he possesses as to the condition of the viscera of the patients in the early "stages" he describes. Before he can predict what is or what is not present he must enlarge his experience of the "pathology of the living." Then, and not till then, is he qualified to pose as critic: not until then can he speak with full authority. I shall consider it a privilege to equip him with this necessary experience, and to furnish him with the material upon which alone a sound opinion can be based.—I am, etc.,

Leeds, March 22nd.

B. G. A. MOYNIHAN.

SIR,—The diagnostic significance of hunger pain in chronic ulceration of the duodenum is of sufficient importance to render its probable cause worthy of some possible explanation.

As it is practically certain that the pain which is felt in chronic ulcer either of the stomach or the duodenum is associated either with the contact of food with the eroded surface or with the induced muscular contraction, there are a few well-defined physiological reasons why the differentiation of the two seats of disease should be easily made.

In ulcer of the duodenum pain is usually felt from two to four hours after food—that is to say, at that period when the pyloric aperture relaxes. The acid contents of the stomach escape into the duodenum, and the latter undergoes contraction. And here it may be stated that the more indigestible the meal, or the more solid the food taken, the longer are the contents of the stomach retained in that viscus, and, consequently, the greater the interval between ingestion and the appearance of the pain. Patients find that when the pain occurs it is relieved by taking food, hence it has come to be termed "hunger pain." The relief afforded is based on the simple physiological fact that when food is taken into the stomach the pyloric aperture is closed, and for the time being there is a temporary cessation of the passage of the food from the stomach and over the surface of the ulcer, and of any duodenal peristalsis.

Another peculiar and significant feature about pain associated with ulcer in the duodenum is the frequency with which the seizure takes place during the night. Here, again, the probable explanation lies in the physiological fact that when a meal is taken in the evening gastric digestion is delayed during sleep, and it is not for some hours that the stomach ejects its contents through the relaxed pylorus, and the patient is awakened by pain.—I am, etc.,

Glasgow, March 19th.

A. ERNEST MAYNARD.

SIR,—Whilst I have read with great interest Dr. Hutchison's letter, I do not think that he makes out his case. The theory which he has adopted of a regular sequence commencing with hyperchlorhydria, followed by continuous hypersecretion with ulcer as the terminal stage, was first enunciated by Robin in his classical treatise upon diseases of the stomach published in 1901. He also coined the term "hypersthenic dyspepsia" to designate this sequence. This hypothesis, never frankly

accepted by the majority of those working at diseases of the stomach, has recently been further discredited, as later work has shown:

1. It is quite an open question to what extent hyperchlorhydria really exists as such. It is obvious that the percentage of hydrochloric acid found to be present in the stomach contents after a test meal must be the resultant of three factors—the total bulk of gastric juice secreted, the amount of chyme which has passed out of the stomach, and the acid content of the pure gastric juice. It may thus be quite possible that from some abnormality in the pyloric reflex we may have an absolutely normal gastric juice, although the examination of the test meal will show hypochlorhydria. The converse is, of course, true. With modern methods of estimating the amount of gastric juice secreted, the whole question of the acidity of the gastric juice will need revision.

2. It is practically certain that in the cases which present what we know as symptoms of hyperchlorhydria, there must be some factor in addition to the excess of acid to account for the pain. The theory that the pain is directly due to the excess of acid is absolutely contradicted by known facts. In the first place, we often meet with cases which are absolutely without pain, although the hydrochloric acid content of the stomach contents is very high. Dutton Steele found acidity of over 70 in 3 cases without symptoms; Stockton has repeatedly found acidity of 100 in similar cases; Kauffman in 19 cases free from gastric symptoms found an acidity of over 70 in 10 and of over 100 in 2. Similar observations have been made by Gintli, Schule, Meyer, Brandeburg, and Illoway. In the second place, Soupault, Verhaegen, and Luigi Sansoni have recorded numbers of cases in which the hyperchlorhydria symptoms having been cured by appropriate measures, the hydrochloric acidity of the stomach was found to be just as high as ever. Thirdly, in many cases presenting the hyperchlorhydria syndrome, the hydrochloric acid content of the gastric juice was found to be subnormal.

3. If there is one thing more certain than another it is that when you find more than 50 or 60 c.m. of hydrochloric acid-containing fluid in the stomach before breakfast, together with food residues, there is practically always an ulcer close to the pylorus or some contraction of the pylorus from adhesions due to old ulceration. If this is associated with rigidity of the rectus muscle, with or without the characteristic tender spot and hyperaesthetic skin area, our confidence in the diagnosis will be correspondingly increased.

I think that, taking all the facts which I have mentioned into consideration, we are justified in concluding that the pain of hyperchlorhydria is not due to the amount of hydrochloric acid in the stomach, but to the presence of some other factor, which may be an ulcer or a hyperaesthetic condition of the stomach or even of the solar plexus. As regards the hunger pain, which is so characteristic of ulcer of the duodenum, Dr. Hutchison evidently confounds it with the hyperchlorhydria pain which I have been discussing. The hunger pain is *sui generis*, and comes on when the stomach is empty, and is probably of purely mechanical origin, due to the dragging of the retracted empty stomach upon the adhesions by which the ulcer is attached to surrounding parts. On introducing food into the stomach the tension is relaxed, and the pain ceases.

In conclusion, whilst cordially agreeing with Dr. Hutchison that the great majority of cases of dyspepsia met with in practice are due to functional disorder and not to organic disease, I think that there is much more chance of hyperchlorhydria being considered functional when the real cause is irritation from a gall stone or a duodenal ulcer than the reverse. It is so fatally easy to be misled by the latent periods which appear characteristic of these affections into deluding oneself that you have cured a functional disorder.—I am, etc.,

London, W., March 21st.

GEORGE HERSHELL.

DIAGNOSIS OF DUODENAL ULCER.

SIR,—Mr. Alexis Thomson, in his paper on the diagnosis of chronic duodenal ulcer, lays stress on the cause of pain as being due to peristalsis and not to the contact of the hyperacid residue of digestion with the ulcers.

It is difficult to reconcile the explanations he puts forward with personal experience.

As a sufferer for seven years I invariably obtained instant relief by neutralizing the hyperacidity; a strong saline draught would not stop the peristalsis of the stomach—if anything, it would rather stimulate it—and yet the pain disappeared without fail. Again, if the stomach be washed out during the crises of pain and freed from the acid-sour residue, pain will at once subside and be replaced by a feeling of comfort, and if the patient now takes a meal the pain will not return until two or three hours afterwards, when digestion is finished and the acid residue is again passing over the ulcer.

A symptom which I have observed in others and have experienced, but which I have never seen mentioned, is that at the time the pain and pyloric cramp is at its height there is often a copious flow of saliva; it will run from the mouth in a stream, if the patient swallows the saliva he will experience instant relief. This always struck me as being Nature's relief.

After operation the pain disappears long before the ulcers could possibly have healed; is not this due to the acid being neutralized, or, by passing through the new opening, not coming in contact with the ulcers? At the same time the patient is conscious of markedly increased peristalsis.

Hyperacidity might be a contributory pathological cause, but it would also appear that the presence of an ulcer in an organ would necessarily increase its secretion; such is the case in ulcers of tonsils or mouth and also in dysenteric ulceration of the bowels, etc. Therefore it is reasonable to conclude that a gastric or duodenal ulcer is the cause of hyperacidity.—I am, etc.,

Falmouth, March 25th. A. WRIGHT, Major R.A.M.C.

PULMONARY TUBERCULOSIS IN CHILDREN.

SIR,—In Dr. Walter Carr's letter in your issue of February 20th he states that my figures from foreign sources in regard to the number of children found at autopsies to have tuberculous lesions in the lungs correspond, in the main, to those from London hospitals.

The figures I gave were for children dying of various diseases, or from accidents, and Dr. Carr now admits that autopsies show that some 30 per cent. of children dying from various causes show tuberculous lesions in the lungs. But if these children are representative of the general child population, then it follows that 30 per cent. of children living have pulmonary tuberculosis.

Deaths certified as being from phthisis in children are far less than 1 per cent.

If these children are not representative, then we must hold that the existence of this pulmonary tuberculosis has been the determining factor in causing the deaths—that is, that children with pulmonary tuberculosis are specially liable to die from other causes. This is true to a certain extent for one or two diseases, such as measles, but cannot hold for deaths from diphtheria, accidents, etc. Let us grant, for the sake of argument, that it is a factor in so high a proportion as one-third of the cases. That only brings our percentage down from 30 per cent. to 20 per cent. Hence it appears clear that autopsies show that at least 20 in every 100 children have pulmonary tuberculosis. I say that we ought to be able to detect this disease during life in children; and if Dr. Carr would spend a few days examining school children I am certain he would do so. As it is, he probably only sees children seriously ill, and hence forms an erroneous conclusion.

My "rule of three" method of calculation has been much criticized. In my original paper I stated that the deductions were only meant to be very roughly approximate, and that it would not affect my argument if the results were halved or quartered.

I have only ventured to urge that we should diagnose this disease as soon as physical signs appear. Sir Clifford Albbutt would think I am deplorably behind the times, for he writes me that "the case in which physical signs have appeared without systematic treatment is a bungled one."

On referring to my notes on 65 autopsies in an asylum on persons found to have pulmonary tuberculosis (in 63 of which tubercle bacilli were found), I find that the existence of this disease was diagnosed as long as one month before death in only 10 cases. Is it not time that some one called the attention of the profession to our failure of diagnosis in this matter?—I am, etc.,

Droitswich, March 22nd.

MARY HAMILTON WILLIAMS.

INFANTILE MORTALITY IN POOR LAW INSTITUTIONS.

SIR,—The figures published in the Minority Report of the Poor Law Commission as to the Infantile Mortality in Workhouses and Poor Law Infirmarys obviously require careful investigation. There are, however, certain considerations which make it highly probable that the deductions drawn from them by the Minority Commissioners and by some writers in the public press are not justified. For instance, the whole of the figures after the first three weeks of life are obviously erroneous, because the report states that they have been obtained by assuming that the death-rate amongst the children discharged is at the same rate as amongst those detained in the infirmary. The fact is, however, that infants are not detained as a rule in the infirmary after the first three weeks unless the child is ill. Obviously, if the death-rate of these sick children is assumed to apply to the healthy children discharged, the death-rate so obtained will be very much greater than the real death-rate. Again, some of the figures are so extraordinary that they can hardly be accepted until verified and the methods of recording the births and deaths have been critically examined.

However, confining one's attention to the death-rate during the first three weeks of life, the figures given show that the death-rate is higher in infirmarys and workhouses than it is amongst the general population. The cause of this is fairly obvious. Amongst the women received into the maternity wards of workhouses and Poor Law infirmarys are many who have been underfed and overworked throughout the period of pregnancy and many who have been admitted to the infirmary owing to syphilis and other diseases: the majority of them are unmarried, and in the case of many, owing to disease or to deliberate interference on the part of the mother, the child is born prematurely. It is manifestly unfair to compare the infantile death-rate of such a population with the infantile death-rate of the general community. The same influences do not affect to anything like the same extent the voluntary lying-in hospitals or maternity charities; first, because the benefits of such charities are usually reserved to respectable married women, and, secondly, because pregnant women suffering from concurrent disease tend to be weeded out from the clientele of such charities and sent into Poor Law infirmarys and general hospitals. Nevertheless, one lying-in hospital, quoted in the report, shows a mortality-rate of 59.3 per 1,000 for the first fourteen days of life, as compared with a mortality-rate for the same period in Poor Law institutions of 46 to 53 per 1,000.

How impossible it is to find any certain conclusions upon the figures supplied is well shown by the returns obtained by the Minority Commissioners from the Plaistow Maternity Charity. In this charity only 15.33 per 1,000 of the children died during the first fortnight—that is, about half the infantile death-rate in the general population of that period. From this the writers of the report draw the conclusion that it is better the mothers should be attended in their own homes than sent into hospitals or infirmarys. On the same lines one could argue that, in order to reduce the infantile death-rate in the general population, all mothers should be confined in what the Minority Commissioners describe as the "poor and wretched homes" of Plaistow.—I am, etc.,

C. T. PARSONS.

Fulham Infirmary, Hammersmith, W., March 19th.

SIR,—With reference to Mr. F. Lawson Dodd's letter of March 6th concerning the high infantile mortality in workhouses, as suggested in the Minority Report, great publicity on this subject has lately been given in the public press (*Daily Mail*, March 3rd) by the Honourable Sydney Holland and others. But this paper apparently does not wish to publish any reply from the other side. In answer to these statements, and on behalf of one of the many people engaged in Poor Law work, I would like to point out that the high infant mortality complained of is not found in every workhouse. Of the 103 children born in Oulton Workhouse, Lowestoft, during the past ten years ending Christmas, 1903, there were only six deaths during the first year of life, and of these five died within the first fourteen days of life, death being due to some unnatural weakness present at birth, which could not have been influenced by the child's surroundings. This only deals

with very small numbers. But, nevertheless, it gives an infantile death-rate of 58.2 per 1,000 births, which is quite different to 330 per 1,000, as is stated to be the usual rate in workhouses. Further, it is less than half that for the population at large, which is 121 per 1,000.

The fact that most of the babies born in workhouses are illegitimate may account to some extent for the high death-rate in some institutions. Of the 103 children mentioned above, the large number of 97 were illegitimate. Again, in these cases, the mother has so often weakened herself by abortifacients and the anxiety caused by her condition, to which is often added venereal disease, that the infant has a poor chance to survive.

It is extremely difficult for anyone well acquainted with the conditions that exist in the homes of some of the poorer classes to believe that children living in these surroundings can have a better chance of surviving than children in an institution under the constant supervision of a Local Government Board inspector, a medical man, and trained nurses.—I am, etc.,

DUDLEY W. BOSWELL, M.D.,
Medical Officer to Oulton Workhouse Infirmary and
District, Lowestoft.

March 23rd.

THE TREATMENT OF SCHOOL CHILDREN.

SIR,—If one may judge from the newspaper reports of the meetings of various education authorities, it would seem to be urgently necessary for the members of the medical profession to realize that such developments are taking place as will vitally affect their interests in the future. At the present time many education committees are actually in the process of negotiations with lay hospital committees for the services of the medical staff of the hospital, and if any uniform action is to be taken by the profession it is necessary that such action should be organized at once.

There appears to be no reason why the existing charities should not be used for suitable poor cases discovered during medical inspection of school children, so far as is possible with their present funds and arrangements. In fact, the help afforded by medical inspectors in sorting out cases requiring attention should result in the prevention of a considerable amount of waste. Even this, however, is a matter that should be carefully considered. But it does not require much consideration to convince one that the medical profession should permit no extension of these charities by means of public money in order that these cases may be dealt with. All arrangements for the necessary additional treatment that is required should be made between the public authorities on the one hand and the medical profession on the other, without the intervention of any third party in the form of lay hospital committees.

Of course the whole problem is greatly complicated by the long association of the medical profession with charities and charitable institutions in a manner in which no other members of the community are associated. The fact that the medical profession has for so long given services instead of money to charities is the key to the situation, and the question naturally arises whether the present time is not opportune for the medical profession to cease to give services at these institutions as charity. It is doubtful whether any other step would effectually prevent the further exploitation of the profession by the public.—I am, etc.,

Winchester, March 2nd.

ROBERT A. LISTER.

INSURANCE AGAINST COSTS AND DAMAGES IN CIVIL ACTIONS.

SIR,—In consequence of the demand which has lately sprung up for insurance of medical practitioners against the risk of pecuniary loss when adverse verdicts, involving payment of plaintiff's costs and "damages," are returned against them in civil actions in their professional work, the Council of the Medical Defence Union has concluded arrangements with a company of the very highest repute—the Yorkshire Insurance Company—for such indemnity. All members of the Medical Defence Union can now, by payment of a yearly premium of the small sum of 7s. 6d., effect insurance up to the limit of £2,000, and for a payment of 9s. up to the limit of £2,500—in any case defended by the Union in this respect. For fuller particulars and

general conditions members are referred to the Secretary of the Yorkshire Insurance Company (founded 1824), Bank Buildings, Princes Street, E.C., to whom all applications by members of the Union for policies should be made.

The Medical Defence Union will, as heretofore, guarantee the legal expenses connected with the defence of their members in any case taken up by the council, and conduct such defence through their solicitor and counsel; the Yorkshire Insurance Company will, in addition, guarantee the costs ordered to be paid and any damages up to £2,000 or £2,500 respectively in any individual action in which a verdict adverse to the member defendant is obtained. Thus a complete guarantee against pecuniary loss, up to these limits, to an individual member of the Medical Defence Union is secured in this respect; and further, by effecting the insurance, the members of the medical profession will, I hope, no longer be harassed by appeals to their charity for defraying the expenses incurred when actions are recorded against the individual practitioner concerned, and this will undoubtedly be a great gain individually and collectively.—I am, etc.,

A. G. BATEMAN,
General Secretary, Medical Defence Union,
London, W.C., March 21st.

RURAL NURSING ASSOCIATIONS.

SIR,—Dr. Milligan's excellent letter in the *JOURNAL* of March 13th exactly illustrates the manner in which my "withers" were wrung, under a nursing committee, and I am glad that attention has been called to the matter in such an able manner. I have had the unfortunate experience of being so handled by a local committee of influential ladies that, though being on the committee, the nurse was always upheld on occasions when she interfered with my patients, and took upon herself to criticize my methods and to attend surgical cases without my consent. It is absolutely true that the nurse touted for patients, and in every way tried to make herself of much importance. Also the nurse would leave a case when she thought proper, and thus sometimes endangered the life of her patient, on some occasions, because the rules of the home from which she was sent were that she was not to stay longer than a certain time at one case. Thus the committee and the home controlled her, and the doctor and patients were without her help when it was really needed. I trust the British Medical Association will seriously give their attention to this matter.—I am, etc.,

March 19th.

VICTIM.

A MEDICAL DEGREE FOR LONDON STUDENTS.

SIR,—Graduates of the London University should be grateful for any adverse criticism of the extraordinary proposals of the Conjoint Board, and the inherent absurdity of the scheme could not have been more ably exposed than in Dr. Mercier's letter. I am sure, however, he is mistaken when he says that the crux of the matter is the matriculation examination. Many years' experience has taught me that a very considerable number of students matriculate, and even pass the preliminary scientific, and subsequently decline graduation at the University of London. The fact is that the scope and character of the professional examinations is such that graduation means in every case one, and in many cases two, extra years added to the curriculum. This price the average student will not pay, and his objections are often strengthened by the average parent. The present agitation for an easy London degree has arisen contemporaneously with the establishment of the new provincial universities, and the consequent depletion of the London schools. London has only two advantages to offer a student: One is its unrivalled clinical material and teaching, and the other is its highly considered degree. Post-graduate schools have practically destroyed the first advantage, and if the second is to be destroyed the number of London students is not likely to increase. Why should a provincial student come to London to work for a degree which will be no better than any other? The grievance of the average London student is no doubt legitimate and pressing, but little will be gained by degrading an old and valued degree to meet it. Robbing Peter to pay Paul is an ancient and attractive process, but results gained in that way have not in practice proved particularly satisfactory.—I am, etc.,

Wanstead Park, March 18th.

A. CAMPBELL STARK.

THE PREVENTION OF DEATHS BY BURNING IN CHILDREN.

SIR,—Dr. Parry, in his letter on the prevention of deaths from burning in children, omits to mention celluloid collars. These dangerous things are worn very commonly by children in the country, and I know of a case near here where a child was badly burned when wearing one, owing to the collar coming in close proximity to a candle flame.

There is no doubt an impossibility confronting the attempt to prohibit the sale of flannelette, and I suppose in a minor degree of celluloid collars, but it might be possible to legislate so that the dangers which attend both these substances should be printed and sold with them.—I am, etc.,

CHARLES W. EMLYN.

Culworth Hall, near Banbury, March 20th.

THE TREATMENT OF CANCER.

SIR,—Referring to Dr. Frankish's letter published on March 13th, p. 694, I had no reason to doubt the statement of my patient that Dr. Frankish had preferred not to treat him. I judged that this was in consequence of the nature of the case and the age of the patient. I had no intention of making any reflection or of being discourteous, and regret that through some misunderstanding I was misinformed.

As regards the other case, this is some four years old. I understood that Dr. Frankish's attendance had been dispensed with, and certainly cannot be responsible for what he was told. I was asked to try my treatment, and did so in company with another medical man. After treating for some time, I found the case in too advanced a stage to hope for a successful issue, and ceased to attend.

I have understood that I was on friendly terms with Dr. Frankish for years before and since this case, and it was not until I saw his letter in your issue that I found he considered himself aggrieved.

I at once wrote him expressing my regret that he should feel offended at anything I had unwittingly done.—I am, etc.,

Accrington, March 23rd.

JAS. FENWICK.

THE NATIONAL SERVICE LEAGUE AND THE MEDICAL PROFESSION.

SIR,—Now that the National Service League is seeking to explain and extend its principles throughout the country, it occurs to me that the medical profession have it in their power to render this excellent organization a most powerful help. It may, I presume to think, be taken for granted that the vast majority of the profession is in favour of those principles as enunciated by the league. The immense influence that can be exerted by them, collectively or individually, cannot be gainsaid. The profession is as directly interested in the defensive conditions of the empire as the rest of the community, and, I claim, is second to no other body in its loyalty and patriotism. With confidence it is, to the physical aspect of the subject and the application of those principles to the growing boys and youths, that I would specially make my appeal. The probable beneficial result by drill and other gymnastics is quite sufficient reason for substituting the word "shall" instead of "may" for a course of military training. I would, therefore, plead for the attention of every member of my profession to this subject, and at the same time ask also that the political, moral, and social features should not the less be a strong recommendation in its favour.—I am, etc.,

J. SELWYN COWLEY, J.P., M.R.C.S.

Upton-on-Severn, March 20th.

DR. LOUIS C. PARKES, Consulting Sanitary Adviser to the Commissioners of Works and Public Buildings, has been nominated a member of the Royal Commission appointed on March 23rd to assist the Board of Trade in the organization of exhibits illustrative of British arts, industry, and agriculture at the forthcoming international exhibitions at Brussels in 1910 and at Rome and Turin in 1911. As the result of the recommendations of a Board of Trade committee, a special branch of that Board has been established to deal with all matters relating to the participation of Great Britain in foreign international exhibitions in the future. The Royal Commission now appointed, with the Prince of Wales as president, and Lord Lytton and Sir Swire Smith as chairman and vice-chairman respectively, will co-operate with the Board of Trade in respect of the exhibitions named.

Universities and Colleges.

UNIVERSITY OF EDINBURGH.
IMPROVEMENT AND EXPANSION.

At a meeting of the committee appointed some time ago for the purpose of inaugurating a scheme for the improvement and expansion of the University of Edinburgh the convener reported that the total amount of subscriptions intimated was £47,970. With a portion of the money which had been so subscribed the University had been able to purchase the site of the old Royal Infirmary at a cost of £15,000, and the adaptation of certain buildings thereon to museums, class-rooms, laboratories, and other workrooms for the departments of physics and engineering had been met in most part by grants from the Carnegie Trustees. From Sir Donald Currie's munificent gift a capital sum of £20,000 had been set aside as a fund for the endowment of lectureships in various branches of university education. A special memorial fund had been contributed by Sir John Jackson, in memory of the late Professor Tait, for promotion of research in the physical laboratory. A considerable amount of money was still required to enable the committee to endow chairs of French and German.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN extraordinary comitia was held at the College on Friday, March 19th, the Senior Censor, Dr. Norman Moore, in the chair.

Death of Lady Powell.

On the motion of Dr. Norman Moore, a resolution was passed expressing the deep sympathy of the Fellows with their President on his recent bereavement.

Licence.

The licence of the College was granted to Claude Edward Freer Fortin.

The University of London.

A report was received from the delegates of the two colleges appointed to consider a scheme of conjoint examinations under Statute 123 of the University of London.

The delegates begged to recommend that they be authorized by the Royal Colleges to confer with Representatives of the Medical Societies in London and other Bodies on the University Question.

After a discussion, in which Drs. Herringham, Payne, Mercier, and L. Shaw took part, the recommendation was adopted on the motion of Sir William Allchin.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have been approved at the examinations indicated:

SURGERY.—J. M. Fiske, *J. A. Koch, *W. N. Pickles, *N. S. Shenstone.
MEDICINE.—J. Bramley-Moore, W. C. D'Eath, *H. A. Hancock, *F. O'Neill, *P. N. Pantan, *N. S. Shenstone, *S. H. Watton.
FORENSIC MEDICINE.—J. Bramley-Moore, H. A. Hancock, F. O'Neill, P. N. Pantan, N. S. Shenstone.
MIDWIFERY.—W. C. D'Eath, F. O'Neill, P. N. Pantan, G. S. Richardson, N. S. Shenstone.

The diploma of the society has been granted to Messrs. W. C. D'Eath, J. M. Fiske, W. N. Pickles, N. S. Shenstone, and S. H. Watton.

* Section I. | Section II.

Medico-Legal.

THE RESPONSIBILITIES OF FEVER HOSPITAL AUTHORITIES.

A CASE came before the Sheriff Court in Dundee a short time ago in which a woman acting as legal guardian for her son sued the Town Council for £40. She averred that the sum represented loss and damage sustained by her owing to the defenders refusing to admit her niece to the Fever Hospital while she was suffering from scarlet fever. She also averred that a doctor certified the child to be suffering from scarlet fever, while the medical officer of the Fever Hospital diagnosed the case as one of chicken-pox, and returned the child to her home. The Town Clerk said the contention was whether the municipality or hospital authorities had been at fault. He submitted that it was irrelevant to state they were bound to admit the child without giving chapter and verse for it. The pursuer's agent said his client alleged that the medical officer's diagnosis was the ground of his case. The Sheriff ultimately dismissed the action as irrelevant, and found the pursuer liable in expenses.

MAGISTRATES AND LUNATICS.

AN inquest was held recently at Paulton by Dr. Craddock, coroner for North Somerset, with regard to the death of a woman who committed suicide by cutting her throat. Dr. C. L. Ouseburn stated that he had attended the deceased since November 1st, and on February 23rd advised her removal to an asylum; the local magistrate, however, who made an examination of the deceased, had refused his signature. The coroner,

in summing up, commented very strongly on the action of the magistrate in refusing to sign the certificate, and pointed out the folly of his venturing to place his opinion against that of an expert. He had no doubt this person's life had been sacrificed through the neglect to accept the doctor's advice. The verdict returned was "Suicide during temporary insanity."

FEES FOR MEDICAL EVIDENCE.

DR. CHAS. MERCIER (London, W.) writes: Your definition of an expert witness in answer to "Cheshire Surgeon" (BRITISH MEDICAL JOURNAL, March 20th, p. 759) is new to me, and I venture to doubt whether there is authority for it. You say that his evidence as to the testamentary capacity of a patient would be "ordinary professional evidence. Expert evidence is properly that given by an outside witness who has nothing to do with the case personally." *Aliquando dormitat bonus Homerus*. I think this is a slip.

Evidence is either of fact or of opinion. Any one may be compelled to testify to facts within his knowledge which have a bearing on a litigated case. He cannot escape his obligation to assist the course of justice. If the facts are such as any one is capable of observing, he must give his evidence *gratis*. But if the facts are such as require technical skill to observe, the legislature recognizes that the evidence should be remunerated, and has fixed a statutory scale of fees. But no man can be compelled to give evidence of opinion; and if he consents to give such evidence, he is at liberty to charge for it anything he pleases. If the legal advisers of the litigant consider that the evidence of opinion is not worth what the witness charges, they need not call him; but if they do call him, they must pay him whatever he asks, provided he has named his fee beforehand. If he has not named his fee beforehand, there are certain customary fees for evidence of opinion, fees which are higher than those for evidence of fact, and the witness is entitled to charge, without agreement or no agreement. No doubt many medical men do give evidence of opinion for fees on the statutory scale, but this is because they do not appreciate their rights.

The expert witness is the witness who gives evidence of opinion on a matter on which he has, or is supposed to have, special knowledge; and the fact that he has had to do with the case personally, or even that he is interested in the issue of the trial, does not remove his evidence from the category of expert evidence. The vendor of a picture or of a snuffbox may give evidence of his opinion as to the genuineness and value of the article sold by him, and his evidence, if he is a dealer, is expert evidence. An engineer regularly employed by a mining or water company may give evidence as to the works of the company. So long as his evidence is of fact which any one might observe, he is an ordinary witness. If he gives technical evidence, of fact which no one but an engineer is competent to give, he is a professional witness; but the moment he gives an opinion on an engineering subject, he is an expert witness, and is none the less an expert because he has had to do with the case before.

If a medical witness is called to testify that he saw his patient fall, he is an ordinary witness, and is not entitled to charge a fee for his evidence. If he is called to testify that his patient dislocated his elbow, he is a professional witness, and entitled to charge a fee on the statutory scale; but if he is called to testify that, in his opinion, the patient will never recover free movement in the elbow, he is an expert witness, and may charge what he pleases.

"Cheshire Surgeon" cannot refuse to go into the box and testify to the symptoms he observed in his patient, and for this he is entitled to a fee on the statutory scale; but if he is called to give evidence as to his patient's testamentary capacity, he can charge what he pleases. If he has not yet given evidence, it is not too late to make his bargain. If he has given evidence, he could probably recover such fees as are customarily charged for expert evidence by practitioners of standing equivalent to his own. He is quite entitled to charge for consultations and letters; I always charge for them, and the charge has never been objected to. If his charges are objected to, he can refuse, when in the box, to give any opinion whatever, and no power on earth can compel him to give one; but if he refuses to give evidence of fact, he may find himself committed for contempt of court. He should therefore clearly discriminate beforehand between fact and opinion, and this is not always as easy as at first sight appears. He is much more likely, however, to mistake opinion for fact than for expert evidence.

Of course there are special circumstances which may disentitle a witness of opinion from charging the fees of an expert. A prison surgeon, for instance, cannot claim such fees for testifying with respect to a prisoner under his care. The practitioner who attended the deceased during life cannot claim an expert's fee for testifying in the coroner's court as to the cause of death. But ordinarily the rule is, I believe, as I have laid it down, and if there is authority to the contrary, it is important that it should be cited.

. Much of what Dr. Mercier says is doubtless true, and most professional evidence is really expert evidence. The distinction drawn in the answer referred to is between expert evidence that can be subpoenaed, and expert evidence that cannot. With regard to some of Dr. Mercier's legal opinions we are advised to the contrary. A professional witness sub-

poenaed to give evidence must answer all questions put to him with the approval of the judge. As most of his evidence will often be matter of opinion, it would be impossible in many cases to draw the distinction he apparently relies on.

A CORRESPONDENT, who is a resident officer at a general hospital, writes that he has received a note from a detective stating that the stipendiary wished him to attend at court to give evidence on a case he had attended in the hospital. Evidence was given, as desired, but a fee was refused, the stipendiary stating that he had no authority to pay. Our correspondent wishes to know: (1) Whether he is legally entitled to a fee in such a case. (2) Whether there is any class of police-court case in which he is not entitled to receive payment for giving medical evidence. (3) Whether, in the event of his not attending, unless subpoenaed, he can be compelled to give evidence in any case before being paid.

. (1) He is entitled to a fee if he has been properly subpoenaed. (2) In all cases where he has been subpoenaed he is entitled to a fee. (3) If he is not subpoenaed, he is under no obligation to attend; but if he attends without a subpoena, he may be compelled to give evidence and be unable to recover a fee. The moral of this is that he should refuse in all cases to attend without getting the proper subpoena.

DENTAL PARTNERSHIP.

EXCAVATOR.—Generally speaking it is safer to base a purchase price upon gross returns, say, one and a half years' purchase of gross returns, or whatever corresponds to two years' net returns. Questions may arise as to what is chargeable as expenses in arriving at net returns, but none can arise as to gross returns. Two years' purchase of net returns is a fairly good price, and it would be reasonable to agree that the second half (after the two years) should be sold at the same price. In the event of the senior slackening work this might even be to his advantage, and, in any case, it places the sum to be paid beyond dispute.

Medico-Ethical.

The advice given in this column for the assistance of members is based on medico-ethical principles generally recognized by the profession, but must not be taken as representing direct findings of the Central Ethical Committee.

PUFFING PARAGRAPHS.

OUR attention has been called to some paragraphs of an ostensibly puffing character which have appeared in the *Accrington Advertiser* relative to Dr. Fenwick's treatment of cancer by potassium bichromate as described in a paper by him published in the *BRITISH MEDICAL JOURNAL* of March 6th, 1909. We have made inquiries and have received Dr. Fenwick's "fullest assurance" that the articles referred to have been in no way inspired by him or by any one on his behalf with his knowledge or consent. Dr. Fenwick informs us that as soon as the articles appeared he called on the editor of the *Accrington Advertiser* and personally remonstrated with him on the subject. As we have repeatedly had occasion to point out, doctors have often to suffer much at the hands of injudicious friends. It is difficult to prevent editors of local newspapers inserting any matter that may seem to them likely to interest their readers; they do not understand the feeling of the profession in regard to such puffing. The tone and taste of the articles to be so inserted are certainly deplorable, and we hope that those responsible may be brought to realize that they are doing the practitioner whom they seek to glorify a serious injury.

COLLIERY AGREEMENTS.

ETHICS V. GROATS.—It appears to us from the case as presented, that, in regard to the earlier matter in dispute, as A. had been accustomed to do work for B., it would have been better for A. to allow B. to collect the fee. The matter is one in which an amicable agreement ought to have been come to between A. and B., because it seems hardly fair that A. should always or frequently be on duty for B. without some recompense, and it appears to us that B. expects a very great deal if he expects A. to be always ready to attend serious accident cases for him without a fee.

Coming to the matter of arrangement between the miners' union and doctors, it appears that by an agreement between the profession and the union, the accident work was thrown open to all the medical men in the district at a fee of 2s. 6d. a visit. Under this agreement A. was called to attend an injured collieryman; consequently the ordinary relations between patient and doctor exist. The patient and doctor, both informed B. of the attendance, B. also appears to have been made aware that the patient desired A. to continue, so that under the circumstances B. should hardly have allowed himself to be persuaded to attempt to undertake the case. B.'s best course would have been, if the owner desired him to see the case, to arrange a consultation with A.

We would suggest that this matter of agreement in regard to attendance on patients residing at a distance from the appointed colliery doctor should be brought before the Executive Committee of the local Division of the British Medical Association, and that a business-like contract be drawn up and signed. It would be a great pity that a small dispute, such as this, should be allowed to interfere with what seems hitherto to have been very cordial relations.

THE ADVERTISING OF LECTURES TO MIDWIVES.

C. G. C.—From inquiries we have made, the commendable practice seems to be to advertise such lectures only in the nursing and medical papers.

THE ASSUMPTION OF MEDICAL TITLES.

E. L. Cross.—Although the initial letters M.B.M.E. are of doubtful meaning, and might be misleading if they stood alone, as they are followed by the description "Masseur and Medical Electrician," the owner of the card does not seem to intend to assume any medical title.

MEDICAL CONDUCT.

SINEMAL asks: (1) Is it commendable for a registered medical practitioner to administer anaesthetics to a registered dentist (R.D.S.) who advertises extensively? (2) Is it permissible for a registered medical practitioner to have a financial interest and act in the capacity of expert and consultant to a commercial firm in a secret remedy for distemper for dogs, paying official visits to various kennels?

* We do not think a registered medical practitioner is called upon to act as judge of the professional conduct of a registered dentist. The British Dental Association is a very active body, and will bring suitable cases of objectionable advertising before the General Medical Council. (2) The combination indicated is in our opinion neither desirable nor commendable. As regards its "permissibility," however, we can only say that we know of no rule of any of the various licensing bodies which expressly forbids the practice of which complaint is made.

DOCTORS AND MIDWIVES.

A CORRESPONDENT sends us a cutting from the *Stafford Gazette*, February 27th, 1909, giving an account of the formation of the Billingham and District Independent Nursing Association, the object of which seems to be to import a maternity nurse who shall be independent of the Lincolnshire Nursing Association, and under the sole control of this local body. It is managed by a ladies' committee with a local Justice of the Peace as chairman and other residents as vice-chairman, treasurer, and honorary secretary. According to the rules published all recipients of parochial relief are to have the services of a nurse free of charge; subscribers requiring her must apply to a member of the ladies' committee, but the nurse is allowed to attend a case in an emergency without a special order. As "maternity cases" are named, it is inferred that the rules allow the nurse to attend other cases. Our correspondent suggests that, as it seems to be contemplated that the nurse shall act as an unqualified medical practitioner, he would be open to a charge of covering if he co-operates with her in her practice, and asks our advice.

* The rules are open to that interpretation, but we would suggest that our correspondent should wait and see how the nurse behaves before taking any further steps, and if he finds that she does not confine herself to the proper limits of her practice he can then use his influence to induce the committee to prevent her going beyond the proper work of midwifery and nursing, and only if the committee directly encourages her in her irregular practice should he refuse to co-operate. It is most important that the nurse should act in accordance with the following Rule 9 taken from the suggested rules and information for local associations employing village nurses affiliated to the Queen Victoria Jubilee Institute for Nurses: "In all cases of general sick nursing . . . the nurse may attend a patient on application or in emergency, but must not continue to visit without a medical man being informed. Should the nurse advise the patient to have a doctor and the patient refuse, the nurse may no longer attend this patient except in urgency. She must in any case report the matter to her secretary." Any midwife who takes advantage of her position to practise medicine and surgery should be reported to the Central Midwives Board, as we believe that the Board has no intention of encouraging midwives to become unqualified medical practitioners. Any medical man who co-operated with and aided a midwife to carry on business as an unqualified practitioner in medicine and surgery would be open to a charge of covering, but such a charge would have to be based upon clear proof of the midwife's improper conduct, and could not be inferred from construction of the rules under which she was engaged.

Public Health

AND

POOR-LAW MEDICAL SERVICES.

THE NOTIFICATION OF BIRTHS ACT IN LONDON.

AT the meeting of the London County Council on March 23rd the Public Health Committee reported with reference to the adoption of the Notification of Births Act, 1907, by the metropolitan borough councils. Last year the County Council asked the Local Government Board to consider the desirability of making an order, under Section 3 of the Act, requiring those authorities which had not adopted the Act to do so. The Board had not yet taken the action suggested, and the Committee thought the request should be repeated. There were still eleven metropolitan boroughs in which the Act had not been adopted, and it was essential that the County Council should receive notice of births in every part of London, as the complete information would be most valuable.

Mr. Stuart Sankey moved to refer the report back, on the ground that the borough councils ought not to be coerced into putting into operation an adoptive Act. They had considered their local circumstances, and no doubt knew what was best for themselves. In districts where the infantile death-rate was high the Act should be put into force, but not in others.

Mr. Hunt seconded, and other Moderates supported the amendment.

Mr. Donomey said Islington, which he represented, had no means of carrying out the Act, and added that the measure inflicted considerable hardships upon the medical profession.

Dr. Beaton mentioned the large number of deaths which occurred among infants of less than 6 weeks old, in many cases before their births had been registered. If earlier notification were the rule, health visitors could be sent to give the mothers help and advice.

Mr. Gilbert Johnstone, Chairman of the Committee, replying to the apologists for the borough councils, said that unfortunately the very districts where the Act had not been put into force were the districts with the highest death-rate. The notification of births not only provided useful statistics, but had the further advantage that what children had been born was known, and what midwives had attended the mothers. In cases of puerperal fever the Public Health Committee could take precautions to prevent the midwife from attending other patients and carrying infection. The cost to the boroughs was a trifle, but the result to the nation was of the greatest importance.

Fifteen members voted for the amendment, which was lost by a large majority. The recommendation of the Committee was approved.

HUMIDITY AND VENTILATION IN COTTON-WEAVING SHEDS.

This committee, presided over by Commander Sir Hamilton Freer-Smith, late of the Factory Department, Home Office, and of which Professor Lorrain Smith, Victoria University, Manchester, is a member, has issued its report. The committee was appointed in November, 1907, by the Home Secretary to inquire into and report upon the temperature and humidity necessary for the manufacture of different classes of cotton fabrics, the bodily discomfort arising when heat and moisture are excessive, the means of cooling humid sheds, and the special arrangements necessary for the proper ventilation of dry-weaving sheds. The committee met on forty-four occasions; thirty-seven of the meetings were held in Manchester. Several "humid" and "dry" sheds were visited, and ninety-six witnesses, including medical experts, medical officers of health, and general medical practitioners were examined.

It was no new problem that was referred to the committee, for many of the questions at issue go back thirty-six years, when Dr. (afterwards Sir George) Buchanan reported upon certain sizing processes used in the manufacture of cotton. It was in 1872 that the practice of infusing artificial humidity became common, although steaming had previously to this been in use. In 1882 the operatives complained that their clothes "were so damped by the warm moisture given off by the steam, that, after going out into the open air coughs, colds, and the whole train of lung diseases were contracted, and rheumatism and many other bodily affections. . . followed." This complaint called for a report, which was furnished

¹ Report of the Departmental Committee on Humidity and Ventilation in Cotton-Weaving Sheds. Price 2d.

by Dr. Bridges and Mr. Osborn, one of H.M. Inspectors of Factories, the conclusions being that neither excessive dust nor steam was inseparable from the process of heavy sizing, and that there existed an evil greater than dust or steam, namely, the lack of efficient ventilation in the sheds. All heavily-sized goods are manufactured by the aid of artificial humidity. Mention is made of the reports published in 1887 by Dr. Stephenson, M.O.H., Blackburn, and of the report following the special inquiry which was instituted by the Health Committee of the borough in the following year. These stated that the ventilation of the mills was unsatisfactory, especially in winter, and that while heavy and excessive "steaming" was injurious to the health of persons working in the sheds, light steaming accompanied by proper ventilation was not deleterious. The Cotton Cloth Factories Act of 1889 fixed the maximum limits of humidity permissible for different temperatures and stipulated a minimum of 600 cub. ft. of fresh air an hour for every person employed. Subsequently, owing to representations made by the Weavers' Association to secure total abolition of "steaming," a committee, composed of Sir Henry Roscoe, Sir William Roberts, and Dr. Arthur Ransome, was appointed. In 1897 this committee recommended, among other things, further attention to hygienic conditions in the sheds, purity of the water used for steaming, and as a standard of ventilation 9 volumes of CO_2 in 10,000 of air. Notwithstanding all that was done, so strong has been the feeling among cotton operatives as to not only the great bodily discomfort produced by "steaming," but also its injurious effect on health, that in November, 1906, a ballot was organized by the men's leaders at the request of the operatives, of which the following is the result:

For the abolition of "steaming"	68,154
Against	3,094
Neutral	1,221

These figures eloquently express the feelings of the operatives.

The evidence taken by the new Departmental Committee is said to be convincing as regards bodily discomfort, but so far as injury to health is concerned there is no proof of direct injury, although it is admitted that long-continued work under conditions causing bodily discomfort might possibly in the end be followed by ill health. The committee has not deemed it necessary to recommend the total abolition of humidity. The processes of weaving are facilitated by the use of artificial moisture. In no country other than Great Britain is there any direct legislation limiting the amount of moisture. For the particular class of cotton goods manufactured in Lancashire humidity will be necessary so long as the demand continues for low-priced materials made with inferior yarns.

One of the chief complaints made by cotton operatives is that on leaving the hot atmosphere of the sheds there is experienced a distinct chilling sensation, due to perspiration and absence of evaporation causing dampness in the clothing worn, and that there also result a sense of lassitude and want of energy. Interesting information of a high scientific value was given to the committee by Drs. Haldane, Leonard Hill, Pembrey, A. E. Boycott, and Professor Cadman. It was the opinion of several of the medical witnesses examined, including Dr. Alfred Greenwood, that since the introduction of improved ventilation and clearance of the air of dust the health of the workers had improved. The recommendations of the committee are thirteen in number, and refer, among other things, to fixing the limit of temperature on the wet bulb thermometer at which all admission of artificial humidity shall cease, the limit to be decided by early experiments; amendment of the present schedule of humidity, raising the standard of ventilation in humid sheds from 9 to 12 volumes of CO_2 in 10,000 during daylight, fixation of a standard of purity for the water used for humidifying, and the use of standard hygrometers.

THE HINCKLEY WORKHOUSE INFIRMARY.

THE end of the scandal of the continued existence of the Hinckley Workhouse Infirmary in its present condition seems at length in sight, and on this fact the poor in the neighbourhood of this midland town and all those who take an interest in its good name are to be congratulated. Practically fifteen years have elapsed since it first began, and during all that time the ratepayers have supinely allowed themselves to be represented by guardians consistently neglectful of their duty to the sick poor, while the supreme authority, the Local Government Board, though it is now taking strong measures, is only doing so many years after receipt from one of its own inspectors of a report showing how defective were all the arrangements made by these protectors of the poor. From this general condemnation

it is pleasant to be able to except the medical officer in charge of the workhouse and infirmary; he alone will emerge with credit from this long-drawn-out affair, for, in spite of difficulties and discouragement he has continued to do his best for the pauper patients in his charge, and has not failed to make representations to his authority in the matter. Among other steps, he included in one of his half-yearly reports an unvarnished statement of the real conditions prevailing, and, as recorded in our issue for October 26th, 1907, was promptly hauled over the coals by the guardians for making such unpleasant disclosures in a semi-public document. Towards the end of that year we made a strong appeal to the Local Government Board no longer to palliate the neglect and poor preparation of plans for a new infirmary. On one excuse and another, however, its erection was deferred, and recently the bolder recalcitrants among the guardians persuaded their fellows to defy the Local Government Board and to decide to pigeon-hole the matter again. Thereon the Local Government Board at length took decided action, the net outcome being that now not only the infirmary and the workhouse stands condemned while the union itself is under sentence of death. In other words, the Local Government Board has indicated a disposition, if not an irrevocable decision, to break the union up and form its parishes in new combinations. This has brought the board of guardians to its knees, and it is now ready to give effect to the plans for a new infirmary immediately. Whether this tardy penitence is a real remains to be seen. There seems some reason to believe that it would be better that Hinckley should remain the head quarters of a union, and that in particular it would be a mistake not to leave it as the seat of the workhouse infirmary of the neighbourhood. The town is very easy of access from the surrounding villages, and in addition, it has a good hospital of the cottage type. This latter circumstance facilitates the performance of any operations of comparatively simple nature by the infirmary, while for those of a more complicated character the gratuitous services of specialists in the neighbouring great towns can be secured. This is a decided advantage, and so far as we are aware it could not be secured in any rearrangement of the union which seems possible.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Borough of Ilkeston.—The population in 1908 was 31,512. The birth-rate was 37.7 and the death-rate 14.6 per 1,000, though in the latter no account appears to have been taken of the deaths of residents outside or of non-residents within the borough. The infantile mortality-rate was 147 per 1,000 births, amongst legitimate infants it was 139, and amongst illegitimate as high as 333 per 1,000 illegitimate births. The Medical Officer of Health (Dr. J. J. Tobin) is evidently fully alive to the necessity there is for dealing with this serious condition. While admitting that epidemic diarrhoea, of which disease no fewer than 46 children died in Ilkeston last year, is affected by climatic conditions he points out that it is after all a fifth disease which is bred and spread, not by the sun, but by the myriads of germs that cause the diarrhoea, filth and bacteria to the houses and to the food of the children. He urges more frequent and thorough scavenging with the immediate removal of all manure and decomposable matter. Privy-middens he considers should not be tolerated and tub-closets only if at a long distance from dwelling houses. It is a little disquieting to find that in a town of the size of Ilkeston there is no steam disinfecter and the corporation should seriously consider the advice of their medical officer of health and take steps to provide one. In the apparent desire to avoid a blank page the principal statistical table in the report is cut in two, one portion being on one page and the other on the next while in two instances the heading of a table is not on the same page as the table itself. Table II of the Local Government Board series is intended to give the statistics of wards or subdistricts, but as given in the Ilkeston report it is merely a repetition of five eighths of the information contained in Table I.

THE EMPTYING OF CESSPOOLS.

DR. SPIRO SPERO states that a village in which there is no drainage system, and where each house is provided with a cesspool, was brought within the administrative area of an urban district which it adjoined. It was understood that the urban district council would immediately proceed with the construction of a scheme of sewerage for the village, but instead of doing so some of the cesspools are emptied by the council's cart, and the occupiers of the houses concerned are charged for the service thus rendered.

The question whether the council is entitled to make this charge or not is dependent upon the district council exercising the power vested in it by Section 42 of the Public Health Act, 1875. Under that section a district council may undertake or contract for the cleansing of cesspools, and a fine can be imposed for any delay which occurs in carrying out the cleansing after reasonable notice from an occupier requiring it to be done has been given. If the urban council has not exercised its powers under Section 42, it devolves upon the individual owners of the houses in the village to empty the cesspools.

Obituary.

WILLIAM TILLINGHAST BULL, M.D.,

NEW YORK.

THE death of this distinguished American surgeon has already been announced in the JOURNAL. He had been operated on more than once for cancer of the neck, and a temporary rally was made the occasion of misleading statements in the press that he had been cured of the disease.

He was a direct descendant of Henry Bull, who was twice Governor of Rhode Island and the Providence Plantation, and was born at Newport in 1849. He graduated in arts at Harvard in 1869, and in medicine from the New York College of Physicians and Surgeons in 1872. After serving as interne in Bellevue Hospital, he spent two *Wanderjahre* in Europe, and on his return in 1875 settled down to practice in New York. He was for eleven years, from 1877 to 1888, Surgeon-in-Chief of the Chambers Street House of Relief of the New York Hospital. There he performed one of the earliest laparotomies for gunshot injury, and there he did most of the work which brought him fame as an abdominal surgeon. In 1880 he was appointed Surgeon to St. Luke's Hospital, and in 1883 to the New York Hospital. He also held the office of Consulting Surgeon to several other hospitals. After working for some time as Demonstrator of Anatomy at the College of Physicians and Surgeons, he was in 1887 appointed Professor of the Practice of Surgery in the college.

Dr. Bull was a born surgeon. In his graduation thesis he recommended operation for appendicitis. He was regarded as one of the ablest surgeons and most successful teachers in America; especially in abdominal surgery he had few equals. He was one of the earliest followers of Lister in America. He was somewhat sparing in the use of the pen, but he contributed valuable papers to societies and medical journals, and the *System of Practical Surgery*, by Professors von Bergmann, von Bruns, and von Mikulicz, was translated and edited under his supervision. He was a man of handsome presence, with a winning manner. His integrity of character and high standard of professional honour made him popular among his brethren, while his kindness endeared him to the suffering who came under his care. His loss is deeply regretted by those who knew him.

SURGEON-GENERAL THOMAS TARRANT, M.D.,
C.B., K.H.P.

THIS distinguished officer died at Queenstown on February 3rd, aged 78. He entered the Army Medical Service in June, 1854, and retired in 1890.

The early part of his service was chiefly in the Royal Artillery and 12th Lancers. He saw much war service in the Crimean, Indian Mutiny, and Zulu campaigns (1878-9), for which he had three service medals with clasps and the Turkish medal, and was mentioned in dispatches.

He was a kindly, genial man, very popular among his contemporaries, and the survivors of that generation will learn of his death with much regret.

Dr. THOMAS EVANS, one of the best known ophthalmic surgeons in Sydney, died in January. He was a native of England, and was educated at Guy's Hospital and took the diplomas of L.S.A. Lond. in 1872 and M.R.C.S. Eng. in 1873. Not long afterwards he went to Sydney, and early acquired a large practice. He was one of the founders of the Moorcliff Ophthalmic Institution, a branch of the Sydney Hospital, and was for many years the Senior Surgeon there. He was also Surgeon to the Australian Jockey Club. He was held in the highest esteem by the profession and the public. He died in the 59th year of his age. He was unmarried.

Dr. J. G. METZGER, formerly of Amsterdam, who played a prominent part in placing massage on a scientific footing, died in Paris on March 2nd at the age of 70. He began life as a teacher of gymnastics; then turned to medicine, and for many years had a very large practice as a specialist in massage. In 1888 he migrated from

Amsterdam to Wiesbaden with the intention of founding a sanatorium there. He next went to St. Petersburg, and finally to Paris, where he resided till his death, spending only part of the summer in Holland.

A WELL-KNOWN Hegelian philosopher, who was also a member of the medical profession, has died in Edinburgh, on March 19th. Dr. JAMES HUTCHISON STIRLING, who was a contemporary of Herbert Spencer and Bain, qualified in medicine in 1842, and for nine years practised in South Wales. In 1851 he inherited a modest fortune from his father, which rendered him independent of private practice, and he then devoted himself entirely to literature and philosophy. He lived on the Continent for several years, studying the doctrines of Kant and Hegel. In 1865 he published his work, *The Secret of Hegel*, and afterwards settled in Edinburgh. He wrote many articles on philosophical subjects, besides lecturing on his favourite subject.

The Services.

THE ROYAL ARMY MEDICAL CORPS.
COMMISSIONS FOR CANADA.

THE Army Council has decided that one candidate may be nominated each half-year for a commission in the Royal Army Medical Corps by the Dominion of Canada.

ROYAL ARMY MEDICAL CORPS (TERRITORIAL).
SANITARY SERVICE.

ARRANGEMENTS have been made by a committee of officers for a dinner of the officers of the Sanitary Service of the Royal Army Medical Corps (Territorial Force) at the Hotel Metropole on May 8th, at 7.30 p.m., at which the Right Honourable the Secretary of State for War, General Sir W. G. Nicholson, G.C.B., Chief of the General Staff, Surgeon-General Sir Alfred Keogh, K.C.B., M.D., and Lieutenant-General Sir W. H. Mackinnon, K.C.B., M.D., Director-General of the Territorial Force, will be present as guests.

Those who wish to attend should intimate their intention at once to Surgeon-Colonel William R. Smith, M.D., 37, Russell Square, London.

FIRST LONDON DIVISION.

THE prizes in connexion with the First London Division of the Royal Army Medical Corps (Territorial) were distributed on March 20th at its head quarters in Calthorpe Street by Sir Alfred Keogh, K.C.B., Director-General of the Army Medical Service. In his speech Lieutenant-Colonel J. Harper, the Head Quarters Commandant, recorded the fact that the field ambulance reached its full establishment in February; that two general hospitals which form part of this Division are also complete, and that the First Sanitary Company, though only recently recognized, already has its five officers, and 62 out of the 100 other ranks required. The proceedings ended with a cinematograph display.

Contract Practice.

THE MODERN SICKNESS AND ACCIDENT ASSURANCE
ASSOCIATION.

WE are asked to state that the Accrington and District Medical Society has considered the proposals of the Modern Sickness and Accident Association, Liverpool, and has expressed strong disapproval of the formation of such clubs. The association in question is, according to the printed statement issued, a tontine "run on co-operative and trade-union principles, no shareholders, members only participate in the profits, which are divided annually." It is formed to provide combined sickness and accident assurance, with free medical attendance, medicine, and lawyer, and old-age pensions. The premium rates vary from 2s. a month at ages 16 to 30, to 4s. at ages 50 to 55; members at the last named age are not entitled to old-age pension. The association seeks to obtain medical officers to act at the rate of 4s. per annum, payable half-yearly.

THE London County Council has adopted an order sanctioning the extension of the provisions of Section LXV of the Public Health (London) Act, 1891, with respect to the notification of infectious disease to glanders, anthrax, and hydrophobia in man, and the Local Government Board has expressed its intention of approving the order.

Letters, Notes, and Answers.

BRITISH MEDICAL ASSOCIATION AND BRITISH MEDICAL JOURNAL

The offices of the British Medical Association and of the BRITISH MEDICAL JOURNAL are at 423, Strand, London.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 423, Strand, London, W.C.; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Office, 423, Strand, London, W.C.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Articulate, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, London*.

TELEPHONE (National):—

2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.

2630, Gerrard, BRITISH MEDICAL ASSOCIATION.

2634, Gerrard, MEDICAL SECRETARY.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL *alone* unless the contrary be stated.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 423, Strand, W.C., on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL, and not at his private house.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

COTTAGE HOSPITAL asks for advice in the treatment of obstinate conjunctivitis in a case of herpes frontalis; the ordinary remedies have been used with little benefit.

CAPILLA asks for suggestions for restoring the colour of grey hair which is turning yellow at the ends; the patient is a lady aged 40 who had rheumatic fever when 19 years of age, at which time the hair turned grey.

J. L. asks for advice in the treatment of profuse perspiration from the axilla. The patient is a healthy man engaged in an office, and the perspiration when anything occurs to excite him either in business or otherwise is troublesome.

E. O. S. asks for suggestions for the treatment of diabetes insipidus in a middle-aged female. The quantity of urine in twenty-four hours averages nearly 25 pints, and about 20 pints of liquids are taken by mouth in the same time. Ergot, valerian, bromides, and nitro-glycerine have not produced any marked effect.

CIGARETTE SMOKING.

NICOTINE, who is frequently consulted by youths and men suffering from the effects of excessive cigarette smoking with inhalation, asks for hints as to how to induce a distaste for the habit and to counteract its evil effects.

TREATMENT OF HERPES ZOSTER.

PUZZLED asks for suggestions in the treatment of a middle-aged woman who had an attack of severe shingles two years since. She has since suffered from almost continuous neuralgia of the side. The following remedies have been tried from time to time, but there has never been any improvement for a longer period than a week: The cautery, high-frequency current, tonics of every kind, analgesics, local and general. Careful physical examination has never revealed any signs of organic disease.

LETTERS, NOTES, ETC.

INTER-HOSPITAL FOOTBALL.

In summarizing the results of the Inter-Hospital Cup-ties in our issue of last week, the Middlesex Hospital was inadvertently omitted. The cup was won by the Middlesex for the year 1886-7.

A DISCLAIMER.

DR. N. WALMSLEY (Charing Cross Road, W.C.) desires to disclaim all responsibility for an article which appeared recently in a weekly paper; he is, in fact, exonerated in the course of the article, and the further sale of the issue has been stopped.

VENOUS PULSE IN NECK.

DR. T. WARDROP GRIFFITH (Leeds) writes: In a brief account (p. 720) of a paper I read before the Leeds Division of the British Medical Association on The Venous Pulse in the Neck, an account which, considering that it was written from memory by our excellent secretary, Dr. Allan, is very accurate, there is an omission so important that in justice to myself I should like to see it rectified. The text from which I preached was the pioneer work of Dr. James Mackenzie, and especially his graphic methods of recording the pulsations of the veins in the neck. Of course every one who has

followed cardiac literature at all knows the debt we are under to that distinguished observer, and it would ill become me to read a paper on this subject without a very full acknowledgment not only of his work, but of his personal help and encouragement to me in my attempts to follow up his investigations.

SLEEP AND WANT OF SLEEP.

DR. FRANCIS HARE (Medical Superintendent, Norwood Sanatorium) writes: None of your correspondents writing on the above subject has referred to acromorphone, first suggested as a hypnotic by Charles T. Douglas (New York Medical Journal, March 17th, 1900). Though generally useful in insomnia, it seems an almost ideal hypnotic in the clinical variety which consists in an inability to go to sleep. The dose need rarely exceed $\frac{1}{2}$ gr. given hypodermically; $\frac{1}{4}$ gr. is usually enough. The drug has displaced nearly all other hypnotics at the Norwood Sanatorium. Its use is dealt with in the last (third) annual report of that institution, which is sent post free on application to all members of the medical profession.

THE CAUSATION OF INGROWING TOENAIL AND THE LOCATION OF GOUT.

MR. EDW. C. MASSEY, M.R.C.S. Eng., L.R.C.P. Lond. (Natal), writes: In the BRITISH MEDICAL JOURNAL of January 16th an article by Dr. G. Arbour Stephens, stating or suggesting that the cause of ingrowing toenail is the position of the foot assumed during sleep, as against the orthodox teaching of the textbooks that it is due to the wearing of tight and badly-fitting boots. Should Dr. Stephens's view be correct, we should expect to find this painful affection quite as often in individuals who do not wear boots at all. Now I have had some years of experience in practice in the South Africa natives, principally Zulus, also of Indians, and I have never seen or heard of a case of ingrowing toenail amongst them. The Zulu rolls himself in his blanket to sleep, and, so far as I have observed, usually on his side; he lies on the hard ground in his kraal, which I should think would be more likely to cause the condition than the soft pressure of a bed.

I am fully aware that, especially in the towns, some of the natives wear boots; but it is more out of vanity and a desire to imitate the white man than either for usefulness or comfort. Even in boot-wearing natives I have never seen a case of ingrowing toenail; but this can be easily explained, as the native would promptly remove his boots if causing him pain or discomfort, and would walk without them, the sole of his foot being hard enough to take him anywhere. The Zulu is lower in the scale of evolution than the European, and as yet is not educated up to the point of enduring the agony of a tightly fitting boot simply for the sake of appearance or fashion. But one day he will; let us be patient!

I know that people who always go about with naked feet in the home country are somewhat difficult to find; but could Dr. Stephens say that he has ever seen the malady in question in a person who has never worn boots?

MEDICAL REGISTRATION.

DR. JOHN HARRIS JONES, M.D. Brux., L.R.C.P. Edin., L.F.P.S. Glasg. (Wilkes Barre, Pennsylvania), writes: I quite agree with Dr. Stanley Haynes, when he says, in the JOURNAL of February 20th, that "Section 14 of the Medical Act is most unjust to medical practitioners, and should be repealed." I was registered nearly thirty-three years ago, and have practised most of that time outside of Great Britain. In 1904 I returned to my native Wales, and engaged in practice there until the spring of 1906, when I returned to my present abode. Before leaving, however, I have almost a vivid recollection that I advised the Medical Registrar of my intended change of residence. I did not know that my name was no longer in the Register until I received an announcement last October from Messrs. Chubb, stating that they could not continue having my name appear in their Directory unless I re-registered. After receiving this intimation I immediately wrote to the Medical Registrar, and in due time received a reply, in which he said he had not received my advisement, and enclosed therewith were two long forms to be filled up, witnessed by two registered practitioners, and sworn to before a justice of the peace, to which declaration a £1. the prescriber restoration fee. It is singular and very unfortunate, to say the least, that that occasion was the only inquiry that had been made by the Registrar concerning me during the odd thirty years of my registration.

EXPLOSION OF AMYL NITRITE CAPSULES.

A LAYMAN writes that he has kept a small box of amyl nitrate capsules carefully done up in cotton-wool for some twenty years in a drawer among articles of clothing, the temperature of the room being about 50°. Recently an explosion took place, all the capsules with one exception being destroyed. Amyl nitrate is spoken of, but probably the nitrite is intended, as the former is not used in medicine and is not likely to be supplied in glass capsules. The explosion was no doubt due to slow spontaneous decomposition of the amyl nitrite, a gaseous product, chiefly nitric oxide, being formed; the gas would accumulate in the capsules with increasing pressure until the bursting point of the latter was reached. A similar explosion, after capsules had been kept for three years in a warm climate, is recorded in the BRITISH MEDICAL JOURNAL, March 30th, 1907, p. 787.

THE SEARCH FOR PATIENTS.

IN looking through some papers forwarded to a correspondent a few months ago by the director of the Weidhaas Hygienic Institute Limited, we have noticed a printed form which had previously escaped attention. This form is as follows:

R. B.

Have you Friends who need our Treatment?

If you know of anyone whom you think might derive benefit from the use of our Home Treatment, you will do them and us a great favour by noting herein their names, addresses, and the trouble you believe them to be afflicted with. Upon receipt of the names we will send them information concerning our method of treatment, but will not mention your name unless you desire it.

NAME. ADDRESS. AILMENT.

Please return to The Weidhaas Hygienic Institute, Burgess Hill, near Brighton.

This form affords an illustration of a system which appears to be followed, with variations, by other companies appealing to the sick. It may be remembered that about five years ago we reported that we had received a letter from a firm of pharmaceutical chemists in a provincial town enclosing a postcard received by them from a company, which offered £s. for the name of any patient suffering from diabetes, pointing out that "it is money easily earned." The pharmaceutical chemists who wrote to us expressed their indignation at the attempt to bribe them to commit a breach of confidence, but such a request might not be so regarded by a patient, more especially if the advertiser lays great stress upon his benevolent motives, and his anxiety to benefit as many persons as possible.

The proprietors of the institute referred to seem to hail from Germany; they issue a pamphlet with the title *Dum opus pro*, which is made up mainly of the usual testimonials, but contains also a sort of outline of the physiology of various organs, taken from medical works. The pamphlet does not differ from the ordinary productions of advertising quacks: the terms are said to be very moderate, the more so as it is the rule to make one charge only for the whole treatment. The proprietors taking the risk of its being of long duration. It would seem, however, that this arrangement is not always followed, for in a "Diet Table" headed "Direction for Weidhaas Home Treatment" we find the following:

It is absolutely necessary that all patients, while under my treatment, shall take the "Star Tonic" regularly. (This must be always taken in sips only.)

For Breakfast—Take the delicately flavoured Nutritive Salts Cocoa, boiled in milk (which, being specially prepared for invalids, on account of the great percentage of nutritive salts which no other cocoa contains, is most suitable in your case. . . .

Between Breakfast and Lunch take one or two tumblers of milk. If possible this should always be taken in the form of Kefyr, one of the easiest digestible nourishing and strengthening tonics. (Full particulars of this are enclosed herewith.)

Half an hour before mid-day meal. (From 1 to 2 o'clock) Sip one cup of Star Tonic.

For Mid-day Meal—Make it a strict rule to take regularly green vegetables of some kind, such as spinach, cabbage, lettuce, etc. A fair amount of these should be taken daily. To these may be added a few potatoes, very little meat or fish, and now and then, in the place of the latter, some pulses, such as lentils (Germans are best). . . .

At Tea Time—If absolutely necessary, take a cup of weak ordinary tea or health coffee; better still, take a cup of Star Tonic, some cold toast. . . .

For Supper—(Let this meal be not less than two-and-a-half, or, better still, three hours before going to bed.) Take either Cocoa or Kefyr. . . .

Before going to bed—Always make a point of taking one glass of Kefyr or cup of Star Tonic.

At the bottom of the diet table is a notice to the following effect:

"The above specially recommended articles can be had from the Sales' Department of the Weidhaas Hygienic Institute, Ltd."

In the circular referred to above as enclosed, Kefyr ferment is offered for sale.

We find in *Truth* (Cautionary List, 1909, the following note:

Paul Weidhaas Hygienic Institute, Burgess Hill, Richard Havel, director.—Advertises a home treatment for asthma, consumption, and a variety of other diseases, making the same pretence as the late Drouet Institute of diagnosing the case of applicants by correspondence.

THE TREATMENT OF CHOLERA.

AT page 832 of the issue of the BRITISH MEDICAL JOURNAL for September 19th, 1903, a method of treating cholera, which had proved most successful in his hands, was described by Dr. R. W. Burkill, of Sylhet, Lower Assam. Essentially it consisted in the early subcutaneous injection of morphia (4 grain to 1 grain), followed by careful abstention from promoting action of the bowels, administration of large quantities of water orally or intravenously, and by careful nursing and dieting should a typhoid condition supervene. This article has brought us a communication from Dr. E. Massart, of Moulle, who says that some thirty-six years ago he tried morphia injections of corresponding strength in some cases of cholera, and drew attention to the value of such treatment in a paper published in the *Union Médicale*, October 16th, 1875. The injections, he found, arrested promptly the vomiting, diarrhoea, and cramps, and power to retain liquids quickly returned. Thus his results in a limited number of cases long ago were on all-ours with the later but more extended experience of Dr. Burkill.

THE LIMITATIONS OF A PURIN-FREE DIET.

DR. R. H. BOTHAM (Stamford, Darlington) writes: "Middle-aged's" purin-free diet does not exactly recommend itself, and if there is an easier way of relief most patients, I think, would prefer it. At one time I used to suffer in the same way as he did, with the exception that dental troubles were not prominent. The febrile attacks resembling influenza were a special nuisance, because they incapacitated me for work, as in a lesser degree did the headaches. An ordinary cold in the head, too, was anything but a trifling ailment to me, and never got better under a month. After reading Dr. Leonard Williams's *Minor Maladies*, and especially the chapter on Goutiness, I thought I saw light, and I adopted the following plan with complete success. I gave up all alcohol and drank water copiously, finishing up at bed time with a pint of hot water. The water is that supplied by the Tees Valley Water Board, and is of the soft, peaty variety. This, I think, is a point in its favour for the purpose. I also gave myself about five minutes' deep breathing exercises every morning. This system was intended to aid excretion and to get rid of the gouty poison, or the collaemia, if you prefer that name. I did not alter my diet, except to increase the daily quantity in response to an improved appetite and a digestion that had become unconscious. I have had no more febrile attacks: I cannot remember when I last had a headache, lumbago has disappeared, constipation is no longer troublesome, and the only disgusting circumstance is that I have begun to put on weight at a rate that if maintained will make me quite a noticeable person in the early future. I think a patient could be more easily persuaded to adopt this plan than to restrict himself to the diet of "Middle Aged's" letter.

DR. JOHN HADDON (Denholm, Hawick) writes with reference to the letter of "Middle-aged" in the JOURNAL of February 20th, p. 512: It is, in my opinion, one of the most important articles that has appeared in the JOURNAL since I became a member. It testifies (1) that diet alone can banish many ailments; (2) that his diet takes away the desire for alcohol; (3) that others, seeing how he has improved, are following; (4) his example. From my experience, I believe he might be better with less variety, and, perhaps, a smaller quantity, for he does not give us the quantity he eats, and I feel sure that Dr. Haddon's quantity is "too much" for most people. It is hard to believe that one slice (say 2 oz.) of white loaf, with a cup of tea, is sufficient to maintain health and vigour in an adult, but I met a man who had lived upon that one meal in the day for three years, and went about doing light work, weighing 5 st. in his clothes, and in excellent health. I had discovered that one slice (2 oz.) of white loaf, with green vegetables (4 oz.) was sufficient to keep a man from losing weight who was not working, but that a working man I could not have believed. It is evident that we must study food more than we have, if we would lessen our mortality, which continues too high, in spite of all our medical officers of health have done, and remove those minor ailments which cause so much suffering.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Eight lines and under	4 0 0
Each additional line	0 0 6
A whole column	2 13 4
A page	8 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 423, Strand, London, not later than the first post on Wednesday morning preceding publication; and, if not paid for at the time, should be accompanied by a reference.

N.B.—It is against the rules of the Post Office to receive letters at Postes Restantes addressed either in initials or numbers.

Remarks

ON THE

TREATMENT OF GASTRIC ULCER BY IMMEDIATE FEEDING.*

By EDMUND I. SPRIGGS, M.D., F.R.C.P.,

SENIOR ASSISTANT PHYSICIAN AND LECTURER ON PHARMACOLOGY AT ST. GEORGE'S HOSPITAL; PHYSICIAN TO THE VICTORIA HOSPITAL FOR CHILDREN.

In December, 1906, in a discussion at the Medico-Chirurgical Society,¹ and in the following year in the *Clinical Journal*,² I mentioned the favourable results which had followed the use of the Lenhartz method of treatment of ulcer of the stomach in a few cases under my care. Since then I have had the opportunity of observing more cases treated in this way, and propose this evening to lay the results before you. The cases here reported were unselected, of the ordinary types met with in hospital practice. For the purpose of comparison, a similar number of other cases, taken consecutively from the records of St. George's Hospital during the same period, are tabulated with them.

The essential features of Professor Lenhartz's treatment are:

(1) Complete rest in bed for four weeks; (2) feeding the patient from the beginning of the attack with small quantities of beaten-up egg and milk, the quantities being increased daily; (3) the application of an icebag to the epigastrium; (4) adding to the dietary boiled rice, mince, and other semisolid and solid foods after the first week; (5) the administration of bismuth and iron in suitable form. Of these, the complete rest in bed, the bismuth and iron, and the icebag are commonly advised by physicians; but the plan of allowing food to be put into the ulcerated stomach at the beginning of treatment is contrary to the usual practice.

The method is founded on the view that acid gastric juice delays the healing of an ulcer, even when no food at all is given by the mouth; and that the reparative process cannot proceed satisfactorily in an ill-nourished and anaemic person, such as the subject of this malady commonly is. Experimental researches are quoted in support of each of these propositions.

That the acid juice will irritate an open sore every one will agree. Mathes produced artificial lesions of the gastric mucous membrane in animals, and found that they healed rapidly except when exposed to the action of dilute hydrochloric acid. This result appears to show that healing was not delayed by the presence of a normal amount of acid but of an excess. In the subjects of gastric ulcer, however, it is the general opinion that the normal gastric juice, if secreted, will act prejudicially, and the treatment by nutrient enemata is intended to prevent the secretion of juice which appears when food is introduced into the stomach. But it must be remembered that gastric juice also flows on the thought of food in a hungry person, and it has been stated by Bourget, Winternitz, and Umber that when a nutrient enema is given a flow of gastric juice is excited, and pain is felt in the stomach. Ewald and Michael, however, were not able to confirm the occurrence of secretion. Pain is certainly felt by many patients, and is often referred to the stomach, though in some cases it may arise in the colon. Obviously, if either the thought of food or the irritation of an ulcer may be followed by a flow of juice, harm may be done, for the juice will flow over the raw surface, which is unprotected by the normal mucous membrane.

The second point—namely, that the reparative process cannot proceed so well in an ill-nourished and anaemic person—is self-evident; it is also clear that even if the patient is, as the subjects of gastric ulcer sometimes are, fairly nourished at the beginning of the attack, the treatment by saline injections and nutrient enemata will be followed by wasting, for all who have studied the subject of rectal feeding by means of accurate metabolism experiments are agreed that, although some energy may

be furnished in this way, nevertheless sufficient food to maintain the needs of the body cannot be supplied. Still less is the anaemia from which these patients suffer likely to improve on such a dietary. Quincke and Daettwyler, found that ulcers which healed quickly in normal dogs did not in those rendered anaemic. If food can be introduced into the stomach from the beginning, the recovery from the anaemic condition is likely to be more rapid than if the patient is subjected to a further period of subnutrition.

The objection to immediate feeding by the mouth is that work is thereby thrown upon a diseased organ which, it might be thought on rational principles, should be given a complete rest. Further, it is urged that the presence of food in the stomach necessitates the contraction of that viscus, to pass it on into the duodenum, and that such movement of the stomach walls is likely to dislodge a clot in an opened vessel and cause a recurrence of haemorrhage. To this Lenhartz replies that the danger of a clot becoming dislodged in this way is no greater than the danger of its being dissolved by gastric juice in an empty stomach, whilst if small quantities of protein food are supplied the hydrochloric acid of any gastric juice poured out is neutralized, because it combines with the protein. To this end teaspoonful doses of beaten-up egg and milk are prescribed. Egg albumen rapidly forms a combination with hydrochloric acid. Milk is a food that calls forth less secretive activity in the stomach than any other food. Fat, which is present in the yolk of an egg, is known to inhibit the secretion of juice. So that the particular combination of foods used is that calculated to excite the least possible secretion and to combine most efficiently with the acid of whatever juice is secreted. As it is given in very small quantities at a time, distension of the stomach is obviated and the necessary movements reduced to a minimum. It is probable that distension of the stomach is far more harmful to an ulcer than contraction. The food is swallowed and requires no mastication, and this again keeps the gastric secretion low, for the act of chewing is accompanied by a production of juice.

An icebag placed upon the epigastrium is intended to keep the stomach in a quiescent state. The application of cold has been observed by Rossbach³ to diminish the movements of the stomach. By promoting atonic constriction of the walls, gaseous distension, which might be a cause of haemorrhage, would be prevented. An icebag also relieves pain when present.

The routine of the Lenhartz method is as follows:—The patient is kept absolutely in bed for four weeks, for the first two of which she is not allowed to move from the supine position for any reason whatever. All mental excitement must be avoided. An icebag is kept upon the stomach almost continually for the first two weeks. The dietary consists of eggs beaten up with sugar, or in some cases with wine, and iced; and of milk. These two foods are taken in small quantities at frequent intervals from a teaspoon, the quantity prescribed being spread over the day, and not given at definite meal times. The first day 7 to 10 oz. of milk are given and one egg. The quantity is increased daily by $\frac{3}{4}$ oz. of milk and one egg until $\frac{1}{2}$ pints of milk and six eggs, or in some cases eight eggs, are reached. From about the third to the eighth day raw or almost raw mince is added, starting with an ounce in divided doses, either beaten up with the egg or alone; the next day, if the mince is well borne, 2 oz. are given; in these cases minced beef was used.

From the seventh to the eighth day boiled rice is added, followed by softened bread and later by a small quantity of bread and butter. One or more eggs may now be lightly boiled. The diet is then gradually increased by the addition of mince or pounded fish, with a corresponding reduction of eggs, until by the end of the fourth week the patient is on an ordinary mixed diet containing the common foodstuffs with the exception of indigestible solids such as peas or other seeds. The patient is instructed to masticate very slowly. On the twenty-eighth day the patient is allowed to get up, and discharged from the sixth to the tenth week.

For the first ten days bismuth subnitrate is given in doses of 30 grains in water without mucilage twice or three times a day. In these cases, however, the carbonate or the oxychloride was used. From the sixth to the

* Read before the Royal Society of Medicine.

tenth day sulphate of iron is prescribed in the following form:

Sulphate of iron	150 grains
Calcined magnesia	20 grains
Glycerine	1 drachm

Mix and divide into 60 pills.

Two of these are given two or three times a day. Lenhartz increases the dose gradually, giving three for three days, four for four days, up to ten for ten days, and then down again. In some cases arsenic is added. The bowels are not disturbed at all during the first week unless they are naturally opened. An enema is then given and repeated every fourth day during treatment. The mouth should be washed out and attended to regularly.

In my own cases I have usually begun with 3½ oz. of milk and one egg on the first day, and have seldom given the iron pill more than three times a day.

It is claimed for the Lenhartz method that it is suitable for all forms of gastric ulcer except, of course, those associated with mechanical deformities, such as stenosis of the pylorus, and those in which some serious complication, such as perforation, peritonitis, or subphrenic abscess, is present. It is said that the sour regurgitation, the vomiting, and the pains and distress after food disappear in from a few hours to a few days. The method is reported as having been found successful after recurrent hæmorrhages have occurred on rectal feeding.

The diet introduces an amount of food which soon becomes adequate to the needs of the body. A table is given by Lenhartz in which the calories given per diem are shown to reach nearly 1,600 on the seventh day, and 2,500 on the tenth. The actual figures for the first fourteen days are: 280, 420, 637, 777, 956, 1,135, 1,588, 1,721, 2,138, 2,478, 2,941, 2,941, 3,007, 3,073 calories.

It is important that patients should be kept in hospital some weeks after they have reached full diet, for a case cannot be recorded as cured until not only are there no symptoms, but the percentage of hæmoglobin and the weight are normal. Unfortunately it is difficult to keep the average hospital patient in after all symptoms have subsided.

Before attempting a new method it is necessary to ask whether the old is unsatisfactory. There is no doubt that the recognized method of treatment is in many cases extremely successful. It has, however, some serious disadvantages. In the first place, severe cases are subjected to a considerable period of starvation or semistarvation, and the less successful the treatment is the longer is the starvation period extended. The routine when fully carried out is extremely tedious. Dr. Hawkins describes for instance, a course in which four weeks after admission the patient is having only milk, plasmon, arrow-root, and thin bread and butter. Fish and chicken are started six weeks after the mouth-feeding has begun. There has been, however, distinct reaction among physicians against this extended period. During the stage of enemas the mouth may become very foul in spite of careful washing out, and parotitis has occurred (Rolleston and Tebb). Vomiting may be very troublesome in some cases, and it is interesting to note that Drs. Rolleston and Jex-Blake found in one case that on cautiously dieting with solid food and withdrawing the enemas it ceased. The prolonged period of subnutrition is accompanied by considerable acidosis, as evidenced by the excretion of diacetic acid in the urine, as Dr. Rolleston has shown, but stronger than even these objections is the unpleasantness of rectal feeding. In hospital practice this is not such an important point, although the patients and the nurses will take a view very different to that of the physician, who has nothing to do with the actual carrying out of the treatment. In private practice, however, the case is different. Even if the Lenhartz method is not superior to the ordinary method, if it is equally good and not less safe it will prove a boon both to the doctor and the patient when treatment is being carried out at home, where rectal medication is nearly always objected to, and very often inefficiently administered.

The present paper is based upon the details of 33 cases treated by the Lenhartz method, and 34 treated by the ordinary methods. I am indebted to my senior colleagues, Drs. Rolleston, Ogle, and Latimer, for permis-

sion to publish such cases as were not under my care, or were only under my care for a part of their stay in the hospital. The cases were taken *seriatim* and, with the exceptions mentioned below, not specially chosen. The 34 cases treated by other methods are taken consecutively from the hospital records. The exceptions that have been made in both series are those of patients in whom the diagnosis was, in my opinion, doubtful, on the one hand, because the symptoms were not severe enough to justify the diagnosis of ulcer, or, on the other, cases which were thought or proved to be due to carcinoma; and cases severely complicated by other diseases not directly connected with the gastric disease. A few cases have also been omitted in which the patients were treated by immediate feeding, but in a manner widely different to that advocated by Lenhartz. Some of these did well and some badly, but it would be difficult to decide in which series to put them. Five cases, however, are included in the second series in which there were no rectal injections, either saline or nutrient. On the whole, the two series may be taken as similar to one another in type and in severity.

Both series contain examples of the common accompaniments of gastric ulcer—namely, anaemia, carious teeth, and neurosis. The Lenhartz series includes 1 case with albuminuria and 1 with chronic alcoholism. The second series contains 1 patient with ulcer of the leg, 1 three months pregnant, and 1 with uterine displacement.

In considering the advisability of adopting the treatment by immediate feeding, the first question raised will be, is it dangerous? Is there a greater risk of the recurrence of hæmorrhage and perforation than by the usual method of nutrient enemas followed by a graduated milk diet? In the above cases in the first series twenty-five of the patients had hæmatemesis in the attack for which they were admitted, and one had had it in a previous attack. In the 25 cases there was one recurrence on the third day of treatment. The patient was not under my care, and the method was not being rigidly followed, inasmuch as no icebag was prescribed and the patient had moved from the recumbent position when the hæmorrhage recurred. The feeding was discontinued, the patient being put upon nutrient enemas, and a good recovery was made. In the 34 cases treated by other methods, 29 suffered from hæmorrhage in the attack for which they were admitted. There were four recurrences, two on the second and two on the third day. In one case there was bleeding on both the second and third day. As far, then, as these figures go the danger of hæmorrhage is certainly not greater, and apparently less, upon the Lenhartz diet, for hæmorrhage recurred in 4 per cent. of the cases on this diet and in 14 per cent. of the others. In 150 cases with recent hæmorrhage treated by Lenhartz there was recurrence in 10 per cent. whilst in 120 such cases treated by Wirsing with nutrient enemas the bleeding recurred in 18 per cent.

It may be objected that some of these cases were not cases of ulcer but of gastrostaxis, described by Dr. Hale White. This criticism, however, will apply equally to cases in both tables. The researches of Drs. S. Martin, C. H. Miller, and others indicate that the pathology of gastrostaxis and of gastric ulcer is identical, for each appears to arise in a mass of lymphoid tissue. Lymphoid tissue is more abundant in the stomachs of those who are subjects of dyspepsia; the absorption of irritating material from the stomach may cause a breaking down of the follicle, and through the action of the gastric juice an ulcer may result. We know that in the small intestine also the lymphoid patches are the most vulnerable areas. Dr. Hale White has demonstrated that symptoms formerly thought to be definitely indicative of an ulcer may arise from a minute fissure or a group of bleeding spots. These bleeding spots, however, are found frequently in that region of the stomach most prone to ulceration, and it is difficult to say that a group of such small lesions is not an early stage of an ulcer.

We may next consider the question of pain. On the Lenhartz diet the usual result is for pain to vanish entirely within forty-eight hours of the commencement of the treatment, and the diet is so graduated that the risk of recurrence of pain when solid food begins to be taken is, in my experience, less than that of the ordinary method of treatment, in which it is a common thing to

find the patient do well until the attempt is made to take fish or mince.

In the 33 cases treated by the Lenhartz method, in 8 cases pain is mentioned in the notes after the seventh day; 3 of these were transient recurrences; 1 was an extremely neurotic patient who appears in both series, and on both methods of treatment complained of pain during most of her stay in hospital, and another was the subject of nephritis. In 3 other of the 33 cases pain was complained of after the first week.

In the 34 cases treated by other methods, in 11 pain is recorded after the first week; 2 of these were neurotic women, one being the above-mentioned case; in 2 others haemorrhage had recurred; 1 was a patient upon whom gastro-enterostomy had been performed; and there were 6 others about whom no special note need be made except that the pain persisted. In this respect, therefore, the advantage again seems to lie with the Lenhartz treatment.

In none of the cases on this diet was it found necessary to give opium in any form. In one neurotic subject the pain complained of disappeared after the application of a blister.

Weight.—Of the patients on the diet who were weighed on entering the hospital, 8 put on an average of 4.2 lb. each, whilst 6 lost an average of 3.5 lb. each. The figures are of little value, however, as they do not reckon the increase of weight which took place at the convalescent hospital. Of the patients who lost weight, one was a patient who had nephritis, in whom the diet could not be fully carried out, and who lost 6 lb., and another was a case who yielded to neither method of medical treatment nor to operation.

Parotitis is liable to occur in patients being fed by the rectum, even when the greatest care is taken to wash out the mouth with cleansing fluid. It is recorded in 2 of the 34 cases treated by the other methods, but in none of those upon the Lenhartz diet.

The figures are too small to judge of the *mortality*, but it will be seen that no case died upon the Lenhartz diet. There was one death among the other cases.

The *length of stay in hospital* averages thirty-four days in both sets of cases. In this connexion it must be noted that many patients are sent from St. George's Hospital to the convalescent hospital at Wimbledon at a much earlier date than it would be possible to send them to their homes. This figure, therefore, cannot be compared with hospitals not having a convalescent branch of their own near at hand. Cases of gastric ulcer do uniformly well at the convalescent hospital, and almost invariably put on several pounds weight. Fourteen of each series were sent to Wimbledon at the end of their stay in the hospital.

Especially instructive is the comparison of the *number of days in the two sets of cases before the patient reached a diet containing meat or fish*. Among the patients treated on the Lenhartz system, 14 were upon the ordinary diet of the hospital, containing meat, fish, and potatoes, before leaving, the average time taken to reach this standard being thirty days; 11 cases left the hospital on a fish diet, which includes potatoes, having reached this diet in an average of twenty days from the commencement of treatment; 6 other cases were taking fish, but not the full fish diet, when they left the hospital. In the 34 control cases the result is very different; only 4 cases took the full ordinary diet before leaving the hospital, having reached this stage in an average of twenty-three days; the majority (namely, 22 patients) did not reach the stage of meat, leaving the hospital on a fish diet, which they reached in an average of twenty-two days after admission; 7 others were taking fish, but not the full fish diet. The average period before taking fish in these cases was seventeen days. From a consideration of these figures it is evident that the Lenhartz method of feeding enables the patient to take an ordinary diet without pain in a shorter time than treatment by nutrient enemata and a graduated milk diet.

In two of the cases in the first series, and two in the second, resort was had to *gastro-enterostomy*, which should be performed when medical treatment has repeatedly

failed. In one further case in the first series the operation has just been done on my advice in a quiescent interval, as, although the patient responds excellently to medical treatment, she has had several recurrences. A small ulcer was found on the lesser curvature, adherent to an indurated area of pancreas.

It is important to bear in mind that the medical treatment of this disease should be carried out with as much care and precision as is required for surgical treatment. If this be done it will be found to be more efficient than many surgeons appear to think. As I have pointed out elsewhere, any patient who has been treated on milk or upon nutrient enemata, and has not recovered, is regarded by some as a fit subject for surgical operation. Whilst not minimizing the beneficial results of gastro-enterostomy in intractable cases, it must be pointed out that this operation is not an infallible cure for gastric ulcer. In the present small series it will be noted that three of the patients reappeared for treatment after this operation had been performed; another reports that she is still suffering from pain and vomiting. I have also seen a number of others in the out-patient department and elsewhere with recurrence of symptoms. Whether cases of gastric ulcer are operated upon or efficiently treated medically, the majority, for the time being, do extremely well, and the mortality from the disease in nearly all the published series of cases is extremely low. Gastro-enterostomy is not a dangerous operation under ordinary circumstances, but, as Paterson has shown, it is a dangerous operation when performed for haemorrhage. I believe, therefore, that this operation should be done only—first, in cases which, after prolonged medical treatment, do not yield; and secondly, in cases which, having been repeatedly treated by medical means, recur. Perforation and mechanical deformities of the stomach must, of course, be treated surgically.

It will be seen in the tables that in many cases the diet was not carried through in its entirety. My own impression is that the more thoroughly the treatment was applied the better the results; but I need hardly add that no physician will treat even the commonest complaints by rule of thumb, or will have any hesitation in modifying the prescribed formula when it seems best to do so. I have found, however, in the patients under my own care, that the need of such modification is the exception rather than the rule. To a few patients the diet is objectionable. Some prefer the egg and milk mixed, and some alternate teaspoonfuls of milk and of beaten-up egg with sugar. The addition of a little wine to the egg is also recommended, but I have not found this necessary. If the beaten-up egg excites nausea to the point of vomiting, egg-white without the yolk may be used. Instances are reported, and similar ones have come under my own notice, in which, in spite of a strong dislike to the food in the first few days, excellent progress has been made. As a general rule, the patients are comfortable and happy and appreciative of the relief afforded them.

As regards the *subsequent history* of the patients, I have been able, through the lady almoner of the hospital, to hear from 21 of the first series and 16 of the second.

Of the 21 patients treated by the Lenhartz method who have been traced, 9 have been well since leaving the hospital, 9 have had a return of the symptoms of gastric ulcer, and 3 suffer from indigestion.

Of the 16 patients traced who were treated by the usual method, 6 have been well since leaving the hospital, 8 have had a return of the symptoms of gastric ulcer, and 2 suffer from indigestion.

The two series are not absolutely comparable in this respect, for ten months longer has elapsed since the last patient in the second series left the hospital than in the case in the first. As the figures stand, however, we may conclude that the results of the Lenhartz method are at least as durable as those of treatment by nutrient enemata and a graduated milk diet.

The frequency of recurrence in each series is to be attributed partly to the difficulty of keeping hospital patients under treatment long enough. Unfortunately if the patient return to the old conditions an ulcer is liable to recur after either medical or surgical treatment.

A few statistics and criticisms of the Lenhartz method have been published.

Wagner,⁶ in 1904, reported 60 cases, in 35 of which there was no pain from the beginning, and in only 6 did pain last beyond

⁶ Since writing the above I have seen a case in which an extensive chronic ulcer in an elderly woman perforated while under a modified Lenhartz treatment, with a fatal result. The patient had left St. George's Hospital free from pain after this treatment, a fortnight before, but relapsed. The perforation was undiagnosed.

the first week of treatment. In 1 case the pain continued during the whole stay in hospital.

Haberman¹ reported that, in 1906, 135 cases had been treated by Professor Lenhartz in Hamburg, with 3 deaths, each of these fatal cases being very severe or complicated. A recurrence of hæmorrhage took place in 8 per cent., as compared with 20 per cent. in 100 cases treated by the old method. Most were dismissed cured before the eighth week, and no unfavourable effects were produced.

Wirsing² reported 42 cases in 1906, 14 of which had had recent hæmatemesis. In one case hæmorrhage recurred. In 27 of these patients the acidity of the stomach contents was estimated; it was found that during the treatment the amount and percentage of hydrochloric acid was diminished, the latter on the average from 0.14 to 0.11 per cent. Some cases did not show this, and yet progressed as well as the others.

The method of Senator, which has some similar features to that of Lenhartz, may be mentioned here. It consists of the administration of gelatine, butter, and cream from the beginning. He (Senator) stated³ he has reported 50 cases fed upon this diet, of whom 2 died, that is, 4 per cent.

Ewald⁴ uses nutrient enemata for three days after a hæmorrhage, and then gives milk, butter, and eggs, followed by other foods, as in Lenhartz's plan. He reported 34 cases in 1906. The results, however, appear to be inferior to those of the Lenhartz method. In 14 cases death occurred either after operation or immediately after hæmorrhage, and there was a recurrence of hæmorrhage in 7 per cent.

Ewald considers that the Lenhartz method cannot be justified on theoretical grounds and is not worth the risk. The above facts and figures, however, do not support this view, and, so far as data have been collected, it appears to be less risky than other methods of treatment.

Lenhartz in 1906⁵ reported 140 of his cases, all with recent hæmorrhage by the mouth, or mælena. These include some of those reported by Wagner and Haberman. The mortality was 2.4 per cent. He recommends that in such cases great care should be taken not to increase the bulk of milk too rapidly, and in some instances quoted the eggs were given without the milk for two or three days. In one case, by the twelfth day only 17 oz. of milk per day was being taken. The stomach should never be distended. He reports that in two of his patients who died, on the fifteenth and eighteenth day respectively, the ulcer was found to be smooth and healed. He recommends the diet strongly for patients who have recently had a gastro-enterostomy performed.

Lambert⁶ in 1907 published 5 severe cases, all of whom did well on the treatment. One was a woman of 32 years, who, after seven days' rectal feeding and seven days' careful feeding by the mouth with peptonized milk, still had occult blood in the stools and a hæmoglobin percentage of 39, and the question of operation was being mooted. The Lenhartz treatment resulted in a cure. Another patient objected to the diet, even to the point of nausea and vomiting, but nevertheless, after the cessation of the diet for one day, did well. In another hæmorrhage went on until the thirteenth day, and the case was regarded as below the standard limit for surgery, and yet made a good recovery on this treatment. A fourth case, with signs of peritoneal irritation, leucocytosis, and a temperature of 103° to 104°, also recovered. In a fifth case, in which the hæmoglobin was reduced to 20 per cent., in spite of an attack of enteric fever upon the twenty-second day, the treatment proved successful. Lambert's fourth case resembles one which came to my notice after the figures which I have given had been collected. A young woman of neurotic temperament was treated by Mr. G. E. Friend for gastric ulcer on the Lenhartz plan. She had no pain for four days, when vomiting recurred, with rigidity of the upper part of the abdomen. Perforation was discussed; the patient was put upon enemata, and made a good recovery. It is a matter of conjecture whether she would or would not have recovered equally well if, as in Lambert's case, the treatment had been persisted in.

Berger,⁷ in a publication from the Hamburg school, points out that so efficient has the method of treatment been found in the *Spezial-Abtheilung für Magen- und Duodenal-Erkrankungen* that it has proved useful as a method of diagnosis, for in cases which fail to respond the diagnosis has, in many instances, been at fault. He quotes six cases in which the failure of the diet led to the diagnosis of cancer, which was confirmed by operation in four of them and in two by autopsy. In another case hæmorrhage was found to arise from dilated veins about the oesophagus due to cirrhosis of the liver. He says, further, that in cases of pain without bleeding which do not yield, nervous diseases may be suspected.

Schütgen⁸ mentions in 1907 that Lenhartz had then treated 231 patients, with a mortality of 3 per cent. This is about the same as the mortality in 195 cases treated by nutrient enemata by Leube, which was 4 per cent. Leube has altogether collected 556 cases, with a mortality of 2.2 per cent., but many of these were not of the hospital class.

It appears, therefore, that the death-rate of patients treated by the Lenhartz diet is not greater than that of those treated in other ways.

Finally, Mr. Langdon Brown⁹ in a recent paper mentions that he has treated 11 cases by the Lenhartz method with good results in 9 of them.

In conclusion, from an examination of these two series of cases, it may be said:

First, that the Lenhartz method of treatment is not

more dangerous than treatment by nutrient and saline enemata followed by a graduated milk diet. In these particular cases the recurrence of hæmorrhage was less frequent, and there were no deaths.

Secondly, that the pain suffered by the patient in the course of treatment is less on the Lenhartz diet.

Thirdly, the diet gives far more nourishment than can be introduced into the body by nutrient enemata, and is, therefore, more desirable in patients who have frequently been for a long time in a state of semi-starvation, or have suffered a loss of blood, or both.

Fourthly, that in cases treated by this method rectal injections may be entirely avoided. This is an advantage in a hospital, and a still greater advantage in treating cases at their homes, where rectal injections are not only regarded as extremely unpleasant, but are seldom efficiently administered.

THE EARLY DIAGNOSIS AND TREATMENT OF CANCER OF THE STOMACH.*

By W. HALE WHITE, M.D., F.R.C.P.,

SENIOR PHYSICIAN TO GUY'S HOSPITAL.

THERE can be no doubt about the importance of this subject. The stomach is a very common seat of primary malignant disease; indeed, in nearly half of all the cases of carcinoma seen in the *post-mortem* room the primary seat of the disease is in the stomach, and although figures from the *post-mortem* room indicating the allocation of primary cancer to different organs cannot be accurately transferred to the living, for many cancers—for example, of the breast—which can be easily observed are excised early, yet the *post-mortem* figures show that cancer of the stomach is terribly frequent. It causes 1.5 per cent. of all deaths at Guy's Hospital. The necessity—if we are to do any long-lasting good to these patients—of an early diagnosis is obvious, for we know of no medical means of successfully treating cancer of the stomach, and with our present knowledge we know of no other proper treatment for cancer than excision, but my experience is that almost invariably by the time a patient comes into the hospital, or by the time a consultation is sought in private practice, the disease is too advanced for excision.

There are many cases in which an early diagnosis is impossible, for the patient does not seek advice until secondary deposits have developed. Thus it is not uncommon for the patient not to consult a doctor until he has secondary cancer of the liver, and in some such cases the most careful examination and investigation of the history fails to suggest the seat of the primary growth. Still in some cases at least there might, I think, be some improvement in our early diagnosis.

The patient's history is of the greatest importance. Three-fourths of all the cases occur between the ages of 40 and 70, and that in spite of there being far fewer people alive then than at earlier periods. There are an enormous number of persons who suffer from dyspepsia unassociated with any organic disease, but such usually have symptoms of dyspepsia when they are young adults, therefore if symptoms of serious chronic gastric indigestion first appear after the age of 40, organic disease of the stomach should be strongly suspected, and if a comparatively short period of medical treatment does not effect a cure, it may be quite justifiable to open the abdomen to see if a growth is present, and, if possible, to take it away. In all cases of gastric carcinoma the utmost endeavour must be made to diagnose carcinoma of the stomach before the

* Remarks made in introducing a debate on the subject to which the paper relates at the Harveian Society of London.

growth becomes tangible, for usually by such a time the period during which the growth could be excised has passed. There is no doubt that sometimes a simple ulcer of the stomach becomes cancerous; precisely how often this happens is very difficult to estimate. A simple ulcer becoming cancerous may occasionally be seen in the *post-mortem* room, but it is only reasonable to suppose that statistics from the deadhouse would underestimate the number of simple ulcers which became cancerous, for by the time of death the mass of growth is often so great that it is impossible to say whether or not a simple ulcer preceded it. On the other hand, clinical histories are very fallacious; often a history strongly suggestive of a previous gastric ulcer may be obtained from patients who have never had an ulcer. Nevertheless, Dr. W. J. Mayo, out of a large number of operations on the stomach, found that a malignant growth had appeared on an ulcer in about half the cases of gastric carcinoma, therefore a history of previous symptoms suggestive of ulcer of the stomach is a help to the early diagnosis of cancer of the stomach; but I have known a confident diagnosis of this disease made in a patient who gave a long history of ulcer, and who had a considerable mass to be felt in the region of the pylorus, but it turned out that no growth was present; the mass felt was the puckering and adhesion in connexion with a large ulcer. However, in these cases the ulcer itself may demand surgical treatment, and therefore opening the abdomen would be justified.

The commonest symptom of cancer of the stomach is pain, therefore we should be chary of diagnosing this disease if it is absent; on the other hand, constant pain is a considerable point in favour of such a diagnosis. Although the general health of the patient may be misleading, for sometimes it remains good, even when the growth has attained considerable size, yet usually those with cancer of the stomach feel more weak, are much wasted and are more anæmic than those whose dyspepsia is not associated with a growth. The red cells may fall to 3,000,000, the colour index to 0.6, and there may be a small increase in number of polymorphonuclear cells. Loss of appetite, nausea, and repugnance to food are usually well marked quite early in cancer of the stomach. On the other hand, these symptoms are often absent when the indigestion is not due to growth. And we must always remember that the probability of cancer is greatly increased if any or all of these dyspeptic symptoms resist ordinary dietetic and other medical treatment.

Much attention has been directed to the amount of free hydrochloric acid present in the stomach of those suffering from gastric carcinoma. It is best after the fasting of the night to wash the stomach out with some water, then to give a test meal, such as a little bread and butter and milk, and an hour and a half after to siphon out the gastric contents. It appears that in a few cases of gastric carcinoma the free hydrochloric acid is not diminished, and it has been stated that this is especially likely to be the case when the carcinoma has developed on the site of an ulcer. Further, in many other gastric conditions, for example, atrophy of the gastric mucous membrane, and chronic gastritis, the hydrochloric acid may be diminished, although on the average not to the same extent as in gastric carcinoma. Carcinoma anywhere will diminish the amount of free hydrochloric acid—for example, in a case of carcinoma of the penis it was reduced to 0.00078 per cent. (the normal being 0.1951 per cent.). But the presence of carcinoma in other parts of the body is frequently easy of recognition. Therefore, in a case in which gastric carcinoma is suspected, the diminution of free hydrochloric acid is of help in diagnosis; but it must be a considerable diminution, for various diseases other than malignant disease will diminish it somewhat. These results are the outcome of work by Moore, Morton Palmer, and others. The observations must be made by competent chemists, for it is not an easy matter to estimate the percentage of free hydrochloric acid in the gastric contents.

It is hardly necessary to mention that these should be carefully examined under the microscope, for occasionally cancer cells may be seen. Sometimes, too, the presence of a few blood discs or blood pigment, as shown by the guaiacum test, will be of help in diagnosis; but before

relying on the guaiacum test we must be sure that the patient has not recently taken any meat. The occurrence of hæmorrhage for the first time from the stomach in a person past the age of 40, if he gives no history suggestive of ulcer, and has not an obvious cause—such as cirrhosis—for his hæmorrhage, is strongly suggestive of cancer. In 35 to 40 per cent. of all the cases of gastric carcinoma the vomit at some time or another contains blood visible to the naked eye.

In rather over 60 per cent. of the cases of carcinoma of the stomach the growth is at the pylorus, and in a considerable number of such cases there is a consequent obstruction to the exit of food from the stomach. Percussion without artificial distension is an uncertain means of estimating the size of the stomach, and a little succussion is fallacious; therefore these signs should not be relied upon in determining whether the patient has some gastric dilatation as a result of pyloric obstruction, but if a patient is given some bread and milk mixed with bismuth oxychloride and then examined in a vertical position by the x rays with a screen, delay in the passage of the bismuth through the pylorus may readily be seen; and indeed probably the bismuth method may sometimes help us to discover a growth in other parts of the stomach, for the passage of the bismuth in a normal stomach is such a regular uniform motion that, if any of it adhered to the growth or this impaired the regular contraction of the stomach, we might see the unusual movement of the bismuth on the screen. An examination by the x rays may be of great help in the diagnosis of cancer of the stomach, but too much reliance must not be placed upon it as a means of estimating whether the organ is dilated, for the position of the lower border of the stomach is very variable in health. Vomiting large quantities at a time of sour material is evidence of gastric dilatation, but we ought to try to diagnose these cases before the quantity is excessively large. Lactic acid in the vomit indicates pyloric obstruction, for it shows that the gastric contents have remained in the stomach long enough to decompose, and this too is the significance of the Oppler-Boas bacillus. Visible peristaltic movements of the stomach, generally best elicited by flipping the abdominal wall, are a valuable sign, for, as they indicate hypertrophy of the gastric muscle, if they are present we may often infer that the pylorus is obstructed. Dilatation of the stomach may, too, be made out by percussing the organ before and after the patient has swallowed a solution of bicarbonate of soda followed by some lemon juice. With regard to all these symptoms of dilatation of the stomach, it must be remembered that in order to diagnose gastric carcinoma from them we must show that pyloric obstruction is the cause of the dilatation; hence the value of the bismuth method and visible peristalsis.

Even when the growth cannot be removed, or secondary deposits render this undesirable, much benefit often follows a gastro-enterostomy if there are signs of pyloric obstruction. The vomiting ceases; the patient digests his food better and gains weight. Life will be prolonged partly for this reason, and probably because some of the gastric contents will no longer pass over the growth and hence it is less irritated and it will grow more slowly. It is, I think, clear that there are no means of infallibly diagnosing cancer of the stomach in its early stages; but I do believe that by carefully considering a number of points we might sometimes arrive at a diagnosis earlier than we do, and therefore give the patient the chance of excision, for medicines are powerless to cure him. Speaking generally, it is only in the early stages that excision can do any good, for secondary deposits usually form rapidly, and before subjecting the patient to an operation the whole body must be thoroughly examined to ascertain if any can be detected, and special attention must be paid to the liver and the left supraclavicular glands. Further, each individual case must most carefully be considered, for there is no doubt that many persons have had their lives shortened by excision of a gastric carcinoma; perhaps this, however, would not so often have been the case had the diagnosis been reached earlier. Lastly, even if it is decided that excision is impossible, consideration should be given to gastro-enterostomy, for the relief which follows this when the pylorus is obstructed may be very great.

THE EARLY DIAGNOSIS AND TREATMENT OF CANCER OF THE STOMACH.*

By B. G. A. MOYNIHAN, M.S., F.R.C.S.,
HONORARY SURGEON LEEDS GENERAL INFIRMARY.

A DEBATE upon the early diagnosis and the treatment of cancer of the stomach is most necessary, for the disease claims approximately 1,500 victims every year in England; it is seldom that we are enabled to do much to relieve those who suffer from it, and the cases that we have cured are so few as to be almost negligible. It is only by the close association of the physician and the surgeon, and by their united endeavours, that any hope of improvement in this lamentable state of affairs can be entertained. The opinions which I am about to express will probably not meet with the approval of all, may perhaps encounter the strong opposition of some, but they are views which I have been brought by degrees to hold firmly, and I am here to speak of the faith that is in me.

REPORT OF HISTORY (Anamnesis).

It has long been a practice of mine, in eliciting the anamnesis of patients referred to me with any abdominal disorder, to endeavour to disentangle their thoughts from the present phase of the disease, in order to concentrate them upon the very earliest departures from health of which they have knowledge. A little persuasion, a little patience, and constant encouragement are sometimes necessary before the whole story will be told, but the time is well spent, and the inaugural symptoms, which are of the highest significance, are then disclosed. If this course be followed with patients who are subsequently shown, by operation, or autopsy, or by the later developments of their disease, to be suffering from carcinoma of the stomach, all three different types of clinical history will be elicited.

In the first the patient stoutly denies, nor can any persuasion induce him to recall, any earlier illness or suffering in connexion with the stomach. He will say that his digestion has always been of the best, and that all foods have been alike to him, all have been taken with zest, and that "dyspepsia" or "indigestion" has never in the slightest degree troubled him. In this condition of good, even robust, health there has been a forcible and abrupt intrusion of symptoms hitherto unknown. A sudden hæmorrhage from the stomach may occur, one or two pints of blood being brought up, and from that moment there appear the symptoms indicative of a gross lesion of the stomach. The anaemia which follows so free a hæmorrhage persists unduly, and food, especially meats, fat or lean, becomes distasteful. A sense of uneasiness, distress, weakness (it is variously described) is felt in the epigastrium; vomiting may be repeated, weight is lost, and a palpable tumour rapidly develops in the stomach wall. As a characteristic example of this class I will quote the following cases:

Mr. F., aged 34. Sent by Dr. Mitchell, Oldham. Up to nine weeks before I saw him, on October 26th, 1908, the patient had been perfectly well. The closest examination failed to reveal any history of former trouble in the stomach. His father-in-law told me that he was "the heartiest man in Oldham." Nine weeks before he had begun to suffer discomfort one hour after food; there was a feeling of fullness and flatulence in the epigastrium and abundant eructation of gas, which at last was almost rampant in its offensiveness. There was never severe pain, only a sense of "weight and stagnation." The patient repeatedly said he felt as if there were "something in the stomach that would not move on"; and he felt that the food could not get away. Four weeks later he began to vomit, and did so every day for more than a week; then occasionally there was a day when he did not vomit, and when that was so he afterwards noticed food which had been taken the previous day in the vomited material. Vomiting had ceased for over a week before I saw him. There had never been hæmatemesis nor melaena. From the beginning, but especially during the last month, he had got weaker and thinner and very much paler. When I saw him he was profoundly anaemic; his face was of a white waxy appearance, and the mucous surfaces were almost bloodless. In the epigastrium I found a tumour whose upper margin was well defined, but whose lower was indefinite. The tumour moved on respiration; there was no dilatation of the stomach. The con-Boas bacilli were innumerable. I found on opening the abdomen there was a growth along the whole length of the lesser

curvature, and that throughout the stomach there were deposits of growth resembling boiled sago grains. Glands in all directions were enlarged, and there was a very large secondary growth in the liver. He died on December 23rd, 1908. The growth in the liver had increased considerably.

Mr. J., aged 65. Sent by Dr. Malin, Rochdale. Up to August, 1907, he was perfectly well. He was a man who had led a busy life, amassed a fair fortune, and had lived carefully. There had never been any indigestion nor any abdominal disorder of any kind. There was, in fact, as the patient said, "a clean bill of health." In August, 1907, he had a severe attack of hæmatemesis; he did not remember ever having vomited before, and he had never vomited since. After this he was weak and ill and very anaemic, but he gradually improved in appearance and returned to business. He had, however, lost all appetite; he could not take any meat, and soon gave up all solids. Weight was lost rapidly. I saw him on March 14th, 1908. He had the frame of a big man, but his clothes hung loosely upon him. He was very anaemic, and capillary vessels stood out prominently against the white background of his cheeks. He took very small quantities of soups and milk and tea. In the epigastrium a large, ill-defined tumour could be felt. Lavage and examination by test meal showed long stagnation of all the contents of the stomach, which contained blood, yeast, pus, and bacteria. At the operation I found a growth involving the lesser curvature near the pylorus, and, passing behind the stomach adhering to the pancreas, it involved the greater curvature also. There were several sago-like bodies on the surface of the pyloric portion of the stomach. I performed anterior gastro-enterostomy, with slight temporary benefit.

In the second class are placed all those cases in which a clear history of chronic gastric ulcer can be obtained. In some of these cases there has been only one attack, or possibly two or three attacks rapidly succeeding one another within the period of a single illness, followed by a complete abeyance, or at least a complete latency of all symptoms until the onset of the malignant disease. In other cases the patients have had a long series of attacks, in many respects closely similar to the present one, of "indigestion." These attacks have been characterized by pain, appearing always at a definite interval after food, the interval being longer or shorter according to the character of the food taken. After a solid meal the pain appears rather more slowly, but is unmistakably more severe; after a meal consisting of fluids only the pain comes more quickly, is less severe, and passes away more rapidly. The pain varies in its position, but is usually referred to the middle line, where a tender spot can generally be discovered. The left or the right costal margin may be tender, and the radiations of the pain may be to one side or another, or through to the back. Vomiting is not a frequent symptom; when it occurs it brings instant relief, and a habit of inducing it may accordingly be developed by the patient, who is confident of obtaining ease in that way. Attacks are prone to come more often in cold weather, or as a result of a chill, or by reason of increased work, worry, and anxiety. In some cases the evidences of stasis may develop, though they rarely become dominant. The patient, long accustomed to suffering, may be resigned to the restricted diet of a "chronic dyspeptic." One patient—a lady who celebrated her silver wedding a few days after I had operated upon her—had never, within the period of her husband's knowledge of her, eaten one solid meal. The foods usually taken are of the light, easily masticated, and easily propelled foods. In the history of many patients, however, there are "latent periods" during which food can be taken, if not with a keen relish, at least with better appetite and enjoyment than is usual. But after such a period there is again the breakdown, and pain in its characteristic form returns. An occasional indiscretion, even when the patient is quite well, may bring a reminder of the need for care, and certain articles of diet must be sedulously avoided at all times. Experience of repeated troubles has imposed upon the patient the necessity for care in the selection of a dietary. The "attacks" are without question due to a chronic gastric ulcer. When we operate to-day upon patients who recount these symptoms the chronic ulcer can always be found and demonstrated. After a history of repeated attacks, alike in onset, in character, duration, and relief, comes one attack at first so closely resembling all the others that it is with difficulty to be distinguished as having a special significance, but by degrees revealing a sinister importance and leading on by stages, presently to be described, to a condition clearly due to cancer. This group is indubitably the most common. Approximately, two out of every three

* Remarks made in opening a discussion at the Harveian Society of London.

cases in which carcinoma of the stomach is found in my series give a history of this kind. One or two examples may be given:

Mr. M., aged 48, sent by Dr. Wesley Smith, seen by me August 8th, 1908. The patient has been "bothered with indigestion for years." The pain has always been definitely related to the taking of food. His meals have often been hasty; he has "bolted" solid food, and the meal times have been most irregular. After special stress of work, he has often had to "give up entirely" because of an attack of indigestion. Pain has come usually 1½ hours after food, and the food has then begun to regurgitate, and a feeling of great oppression and fullness has been relieved by belching. About an hour after food he had "miserable discomfort," which a hot drink would often relieve. The present attack began about Christmas, 1907, and has continued ever since. He has lost over 4 st. in weight. Recently his discomfort has only been relieved by getting the food back. He is easy when the stomach is empty, and never at any other time. On examination, a tumour is palpable, and on slight inflation peristaltic waves are visible. Operation October 14th, 1908. A large tumour occupying the lesser curvature up to the pylorus, and extending down both surfaces. Partial gastrectomy. The growth was malignant, and had begun in a saddle-shaped ulcer.

Mrs. A., aged 45, sent by Dr. Horsfall, Slaithwaite, seen July 10th, 1907. The patient says that she has suffered from her stomach "all her life." When asked to be more precise she says that she remembers very well an attack when she was 20 years old, and that was not the first. In an attack pain came about one hour after food; the pain was worse after heavy foods, but came more quickly after liquids. Vomiting at first did not occur, has since been frequent, but has always brought relief. No blood has been seen at any time. In the intervals between attacks she feels very well; the longest interval was rather more than a year in duration. The last attack began at Christmas, 1906. The pain was of the same character, but became by degrees more severe. Diet was restricted to fluids, but pain persisted, and recently has been almost constant. Vomiting has been frequent during the last few weeks. Has lost in this attack 20 lb. Does not improve with the same treatment as before. I operated upon her on July 19th, 1907, and performed partial gastrectomy. There was a large prepyloric growth; a great many glands in both omenta, and the right suprapancreatic glands and the subpyloric group were especially large. The patient died in September, 1908, having had three "fits" on the two days preceding her death.

In 3 cases in my series perforation of an ulcer had occurred twenty-six, ten, and four years previously. In the first case the perforation had been of the "chronic" type, and a perigastric abscess had formed. In the others the history suggested that the perforation had been of the "subacute" type, and the conditions found at the operation lent strong support to this view.

Symptoms of Cancer.

This being the early history, what are the symptoms which are present in the final attack which proves to be due to malignant disease? The patient notices, by almost imperceptible degrees, that the relief which has formerly come for a brief period after a meal is curtailed, that pain comes more speedily or is not relieved at all. It is not long, therefore, before food is taken in lesser quantity, and becomes restricted to fluid forms alone. There is often a distaste for meat, especially for fat meats, as observers long ago noticed. The zest for food is lost entirely, and there is often a positive repugnance to it. While the ulcer is still simple there is rarely a distaste for food; on the contrary there is often a feeling of great desire for food, but experience has shown that indulgence is followed by distress or pain. I have commonly heard it said, "I could eat anything, but I dare not." In patients suffering from well-established cancer this is never heard; the cry is always that the thought of food is abhorrent, and it is difficult to persuade a patient to overcome his intolerance. There is, then, little or no freedom from pain, and a sense of uneasiness, or "sinking" in the epigastrium; yet the pain is never severe, is often not a matter of complaint at all. Food which has been taken "lies heavily" on the stomach, and regurgitation of it may occur, and a nauseous, bitter, but not acid, taste is noticed. There is often much flatulence and eructation of gas. There are times when the gas and the vomited matters are unendurably offensive. The lessening of the size of the stomach by the discharge of either gaseous or fluid contents always brings relief. Very early in the attack anaemia is seen; it is not, as it may have been before, the anaemia which can be attributed to a large and noticeable loss of blood; it is rather a gradually deepening pallor, the face seeming of a whiter colour than the rest of the body. It is not infrequent for the colour to be of the faintest yellow tinge, and the

resemblance to the hue of pernicious anaemia is very close. In all such cases there is a continuing loss of blood, as examination of the stomach contents, removed by the tube, or of the faeces, will show. Anaemia is, perhaps, the most striking of all the signs which indicate the onset of carcinoma in the stomach. The appearance of the patient with pallid, shrunken face, and features preternaturally sharp, the skin being dry and harsh and withered, will often rouse the first suspicion of the gravity of his disease. Loss of weight is continuous; at first it, perhaps, hardly attracts attention, but as soon as note is taken of it, a steady and unchecked wasting is observed. General weakness, indifference to many of the affairs of life which formerly held an absorbing interest, languor and lassitude are all seen in greater, than in less, degree. Such is the complete picture seen in the majority of the cases of carcinoma. A discrimination of two distinct types can usually be found in all cases where the pyloric half of the stomach is the seat of disease. These I would designate as cases of "pyloric" and of "prepyloric" growth. In the former the symptoms almost from the first suggest the presence of a hindrance at or near the pylorus. Vomiting is among the very early symptoms, and dilatation of the stomach, with stagnation, and the periodic return of the long-delayed food, occur. These cases are recognized early, owing to the inability of the patient to take food, either solid or liquid, with comfort, and to the overt character of the cardinal symptom, vomiting. The danger is in mistaking, as I have unhappily done, on more occasions than one, the growth for a chronic ulcer. A palliative operation, gastro-enterostomy, is then performed, when a radical operation, partial gastrectomy, is needed. In the "prepyloric" form the symptoms are such as I have already described; they are general and constitutional rather than local, and are, therefore, less compelling in their interest. The ulcer, and the growth which follows it, are found upon the lesser curvature away from the pylorus; the ulcer has probably been, and may often be shown to be, saddle shaped, and consequently a high degree of obstruction does not come till late. The mere presence of a growth on the lesser curvature—or, indeed, of an ulcer also—seems to do something to impede the passage of food onwards, possibly by entanglement of the nerve supply; a zone of muscle of lessened power offers obstruction in some sort, and causes both stasis and vomiting.

In the third group the patients, who are generally between 40 and 45 years of age, give a history which, in all its essential details, is identical with that in Group 2. But there is one significant omission. No history of any illness which can be referred to a structural lesion in the stomach can be elicited. The whole clinical course is comprised in the one sustained illness which, without haste but without pause, has brought the patient into a condition of serious ill-health. The symptoms in their earlier stages are pain, which appears sooner or later after food, and is worse after solid food to such a degree that liquids soon form the whole dietary; occasional vomiting, and possibly haematemesis or rarely melaena, and loss of weight. There is nothing alarming or particularly distressing in the symptoms, but it is their persistence rather than their prominence which finally attracts attention. Wasting anaemia and perhaps vomiting become conspicuous, and at last it is realized that the patient is probably attacked by some serious organic disease.

At the operation carcinoma is found, and, most important point of all, the growth, in my experience, is sometimes found to be in the site of a chronic ulcer. In this group of cases there is no suspicion, clinically, or only a very vague suspicion, that a chronic ulcer of the stomach has ever been present. It is the pathological disclosures which make it probable or certain that in many an ulcer has formed, an ulcer which at the moment of its full development has straightway become invaded by an insidious malignant process. The change which occurs in this ulcer is in every feature the same as that which is noticed in the cases in Group 2; but in these the change comes in the first life of the ulcer, in the others only after it has many times healed and as often broken down again. The following is a good example:

Mrs. B., aged 46. Sent by Dr. McLeod, Outwood. Seen by me October 10th, 1908. The patient had been perfectly well up

to six months before. She then began to suffer pain one to one and a half hours after food; vomiting occurred shortly afterwards, and always gave some relief. There was never hæmatemesis. The pain gradually increased in severity, and latterly had been much worse after solid food, especially meat. At first there were periods during which she felt quite well, but lately the suffering has been continuous, and weight has gradually been lost to the extent of 11 lb. On examination there was a dilated, visibly acting stomach, and a lump the size of a hen's egg was palpable at the pyloric end of the stomach.

Operation.—The palpable tumour was seen to be a mass of malignant glands ("subpyloric" group). On the anterior surface of the stomach close to the pylorus was a hard round scar, with radiating puckers from it. Partial gastrectomy. Recovery. An examination of the specimen showed a large chronic ulcer of the stomach, at the lower part of which the edge was raised into a mass the size of a Barcelona nut. This was malignant, as also were the glands underlying it.

Relation of Gastric Ulcer to Cancer.

In the remarks I have already made I have done something more than hint at the connexion between ulcer of the stomach and cancer. Are we entitled to say that there is any proved connexion between the two? If we are, then chronic ulcer of the stomach must be ranked among the "precancerous" conditions; and if, further, the connexion be proved to be of either moderate or large frequency, cancer of the stomach is surely robbed of some of its terrors, for it is doubtless then to be enrolled among the preventable diseases. What is the evidence? In a previous paper, read before the Clinical Society of London in February, 1906, I collected and analysed all the cases of cancer of the stomach (58 in number) upon which I had operated up to July, 1905.¹ In the last 22 cases a history of chronic gastric ulcer was clearly obtained in 16; in 1 case there had been a subacute perforation of an ulcer on the lesser curvature near the pylorus. In 1 case the "attack" of gastric ulcer had occurred twenty-six years before; in the interval the health had been good and digestion sound, though care had always been exercised in the matter of diet.

Almost identically the same proportion has held good for my later cases, numbering over 100, and I am therefore in a position to say that of all patients operated upon by me for cancer of the stomach approximately two in every three have had a history of previous gastric ulcer. In the majority of those who give this history there has been a constant succession of attacks, similar in all their chief manifestations and brought about by similar causes. In the last attack the symptoms have been of a graver nature, more protracted, not amenable to the treatment, nor relieved by the drugs, which proved successful before; and by degrees it has become unmistakable that this attack is likely to prove of a far more serious character.

From the clinical point of view it is, therefore, certain that we must look for the inaugural symptoms of cancer of the stomach rarely among those whose former health has been good, often among those whose anæsthesia tells sometimes of one, but, as a rule, of many attacks of "dyspepsia" or "indigestion," as they may be called. These attacks of pain come after food, are definitely related to the taking of food, are eased for a time by food, and there are also vomiting, inability to take or temporary dislike for solids, and loss of weight; the attacks, that is to say, are clearly to be referred to the presence of a chronic gastric ulcer. If, therefore, we are to concentrate our attention upon the early symptoms of cancer of the stomach, it is the patient whose stomach has long been a source of trouble to him that must chiefly engage our attention. But it is necessary to say that this patient, who is, so to speak, the most promising candidate for carcinoma of the stomach, can be prevented from developing this horrible affliction by a timely attention to the earlier simple disease. Cancer of the stomach, if it follows in the majority of cases upon chronic ulcer of the stomach, is so far, and in such numbers, a preventable disorder. In the surgical treatment of chronic gastric ulcer by the performance of gastro-enterostomy, or of Rodman's operation, may be the means of destroying the chances of a late malignant change from an early simple condition. It has often been said that "the onset and persistence of dyspepsia in a man over 40 years of age, who had previously enjoyed good health is a suspicious circumstance" pointing probably to the onset of carcinoma. I have found that in such cases the disease is more often simple

than malignant, and that the lesion found is more frequently duodenal than gastric.

I am only too well aware of the doubt, even perhaps of the hostility, with which the suggestion has been received that ulcer of the stomach and cancer stand often in the relationship I have indicated. But impartial inquiry into the history of a long series of cases will support, I know well, the views I have expressed. Clinically there can be no longer any substantial doubt of the connexion. Is there any valid pathological evidence to support the belief which clinical experience has stimulated? I have no hesitation in saying that the pathological evidence now available supports fully the contention I have stated. In what manner should we expect that evidence to be obtained? I venture to answer that it could only be obtained from specimens examined in an early stage of the disease, at a time when the primary simple disease and the later cancerous change can be seen together. It is, then, necessary also to show that the former condition is earlier than the latter. A moment's thought will convince one of the truth that a specimen of this kind is hardly to be found upon the *post-mortem* table in the body of one who has succumbed at last to the steady and unchecked extension of a malignant growth. The only specimens which are likely to furnish valid evidence must be obtained by operation. The best of these specimens are found when a chronic ulcer, as the appearance suggests, is removed by Rodman's operation. Though no suspicion of malignancy may have crossed the surgeon's mind, the pathological examination will disclose the undoubted evidence of early malignant disease in an area where the ancient marks of simple disease are plainly to be seen. In this connexion one cannot but offer a tribute to the remarkable work which has been done in the clinic of Dr. W. J. Mayo and Dr. C. H. Mayo at Rochester. I had the privilege a few months ago of seeing the specimens of partial gastrectomy removed by them, and of having the pathological conditions demonstrated to me. No one who has seen the evidence there produced doubts any more that cancer of the stomach is frequently the offspring of an early simple disease. Dr. W. J. Mayo² has recorded the fact that, in 180 cases of resection of the stomach, cancer was demonstrated to have sprung up in the base of an ulcer in 97, that is, in 54 per cent. My own experience supports this statement fully; indeed I have myself found the percentage even a little higher in my recent cases.

The connexion between chronic ulcer of the stomach and carcinoma I hold, therefore, to be established so far as Group 2 is concerned. Is there any relationship between the acute cases of cancer of the stomach, cases which seem to have in them something akin to an acute infection, and ulcer? There is no history of chronic ulcer in this class of case; the disease seems to begin acutely and to spread rapidly; in my own work no permanent relief has ever followed operative treatment, and the benefit obtained by the palliative operation of gastro-enterostomy is too often quite inconsiderable. Recently I have come to believe it possible that in these cases also an ulcer may be the starting point of the malignant process. The ulcer in such cases is of the "acute" type; one or more "haemorrhagic erosions" are present, and in these cancer is deposited and spreads there with the most intense rapidity.

If carcinoma should be conclusively proved to be the final change in the long series of changes which have led up to and established a chronic ulcer in the stomach, is it not in this case merely repeating the experience we have gained of its habits in other parts of the body? We know how frequently cancer of the tongue develops as a last change in a series of conditions all of which are simple. It is only the bare truth to say that cancer almost never develops in a tongue previously healthy; where a malignant ulcer is present other changes are seen around it, and these have been present, always for months, often for years. Cancer is there only a local exaggeration of or a later change in a condition of things distributed over other parts, or over the whole of the tongue. It is the same with the lip, and with the ulceration of old scars due to burns. The development of cancer on the cornea as a result of the irritation of smegma retained by a too-long and too tight prepuce was pointed out more than a century ago by the first William Hey of Leeds. In the breast the transformation from chronic mastitis to

maligancy is no longer doubted. In the gall bladder it is commonly seen. And instances might easily be multiplied. Surely the one thing of which surgeons feel sure in respect of cancer is that it seems most often to occur in those parts where mild irritation has long been present.

Exploratory Incision.

A review of the cases which have been under my own care has convinced me that though the history, especially in so far as it tells of former attacks of chronic gastric ulcer, may awaken a keen suspicion as to the presence of a carcinoma in the stomach, and though all the contributory evidence to be derived from the chemical examination of the stomach contents may go towards a confirmation of the diagnosis, there is only one means of making an assured diagnosis in an early stage. An inspection of the parts, and this alone, and that indeed not always, can give us the information upon which a probable diagnosis can be made. It is necessary for us to realize that by any other methods than this one a positive diagnosis of cancer in the stage when it is capable of successful treatment is almost impossible. If the patients who are suffering from this most insidious and most terrible disease are to have any fuller prospect of relief, or of cure, the use of the exploratory operation must be greatly increased. I depreciate more strongly, I believe, than most surgeons the adoption of the "exploratory incision"; but every argument and all experience show that in cases of carcinoma of the stomach no other method than this offers any slenderest hope for the betterment of the present deplorable condition of affairs. But before we are entitled to advise any patient to undergo this operation we must be confident that there is a well-grounded suspicion that some condition not admitting of remedy by any other than surgical means will be found.

Indications for Operation.

I think that an operation should be advised in the following circumstances:

(a) In all cases of chronic gastric ulcer. The recent experience of surgeons has shown that a diagnosis of chronic gastric ulcer can be made with great accuracy, and that not only the presence but also the position of the ulcer can be accurately predicted. When repeated "attacks" occur it is idle to consider any other than operative treatment, for nothing else can give permanent relief. In any attack occurring in a patient over 40 years of age the need for surgical intervention is becoming urgent.

(b) When gastric stasis is present. This is a condition the existence of which is easily determined. If there are symptoms suggesting structural disease in a stomach incapable of emptying itself completely in from ten to twelve hours, then the conditions which exist are mechanical, and can be remedied by none other than mechanical means.

(c) When a tumour is present. The tumour may be simple or malignant, but research is better conducted by inspection than by any other means at our disposal.

In these three conditions medical treatment may do something to relieve, it can do nothing to cure. There is accordingly no reason for delay in advocating operation. If this is done, and done early, many cases of carcinoma that now drift quietly into the inoperable stage may be saved.

The position seems now to be this—that there are no signs or symptoms clearly indicative of the presence of gastric cancer; there is no refinement of clinical inquiry nor any endowment of clinical acumen which will enable a confident diagnosis to be made in an early stage; inspection of the stomach during an operation carried out when definite faults in its working are known will permit of the early discovery, or of the prevention of a certain proportion of the cases of cancer. The surgeon must not ask the physician for a sign which will reveal the presence of this disease to him, but he can and should require that those conditions which are only to be remedied by operative measures should be referred to him not in their advanced or terminal stages, but at the earliest moment of their recognition. The success which has followed the surgical treatment of gastric disorders justifies this simple request.

Chemical Analysis of Gastric Contents.

A point which cannot be ignored in any discussion upon the early recognition of cancer of the stomach has reference to the condition of the stomach contents. Much has been written with regard to the value of a chemical examination of the stomach contents in cases of gastric carcinoma. It is my practice to have all stomach cases examined as a matter of routine, and I place some reliance upon the results so afforded. But it is necessary that more examinations than one should be made, and that the circumstances should be changed in some of the examinations. The fluids removed from the stomach after several hours of fasting, after a test meal preceded by lavage, and after a meal consisting chiefly of albumens should be examined. The characteristic result in cases of cancer shows absence of free HCl, a diminished total acidity, the presence of lactic acid, and the presence of Oppler-Boas bacilli. Briefly stated, my opinion is that the early diagnosis of carcinoma of the stomach receives only the slenderest help, if indeed it receives any, from those examinations; whereas, in the later cases, a suspicion of malignancy receives strong confirmation if the characteristic conditions I have named are found.

Conclusions.

I would endeavour to sum up my knowledge of cancer of the stomach, as revealed to me by a study of the cases which have come to me for surgical treatment, in the following propositions:

1. Cases of cancer of the stomach when examined in regard to their previous history may be divided into three groups: (a) Cases, generally acute, in which the symptoms appear suddenly and progress rapidly; the whole history may be confined within a space of four to nine months. (b) Cases in which there is a history of one ancient attack, or of repeated attacks, due undoubtedly to the presence of a chronic gastric ulcer. (c) Cases in which there is no previous history of gastric ulcer; in some of them a condition of "ulcus carcinomatosum" may be found.
 2. The acute cases are not seldom ushered in by an attack of severe hæmatemesis, with or without melæna. It is possible that such copious bleeding is dependent upon multiple hæmorrhagic erosions.
 3. The importance of a history of repeated attacks of indigestion, alike in their origin, course, and termination, cannot be exaggerated. Such attacks are due to a chronic gastric ulcer, which at last becomes malignant.
 4. Cancer of the stomach, in so far as it depends upon a chronic ulcer for its origin, is a preventable disorder. It is probable that two-thirds of the whole number of cases may be so classed.
 5. The final attack is distinguished from former attacks by its lingering character, its rebellion against the treatment, dietetic and medicinal, which has proved helpful before, but chiefly by the presence of a profound distaste for food, anæmia, and a progressive loss of weight.
 6. The chemical examination of stomach contents is of little or no value in so far as early diagnosis of carcinoma of the stomach is concerned. In the later cases, when a possible diagnosis of malignancy is made on the clinical evidence, the results of repeated chemical analyses of the stomach contents afford additional evidence of considerable value.
 7. Surgical treatment should be advised in all cases of stomach disorder where there is obstruction, stasis, or tumour, and in all cases of chronic ulcer; in this way early cases of carcinoma will be found, and radical treatment will be possible.
 8. There are no symptoms, and there are no signs which, individually or collectively, permit of an assured diagnosis of cancer of the stomach in an early stage. In cases where there is grave suspicion an exploratory operation should be advised. Such operations should be practised to enable a diagnosis to be made in an early stage, not to confirm an almost certain diagnosis in a hopeless stage.
- The surgical treatment of cancer of the stomach is now based upon sound principles, as a result of the work of many labourers in different fields. When the growth is seated at or near the pylorus, or along the lesser curvature of the stomach (and these are the cases we are chiefly considering), the anatomical and pathological investigations have indicated certain essentials to be observed in order that the whole growth, and the lymphatic area in

connexion with it, may be eradicated in accordance with those principles now generally held to be necessary in dealing with any form of carcinomatous disease.

After a study of all the factors, we are in a position to lay down the lines upon which an operation for the removal of a malignant growth beginning in the pyloric region of the stomach should be based. It is essential that the whole growth should be taken away, and such a margin beyond the visible and palpable tumour as shall ensure that the outlying nodules are within the lines of section; that all the lesser curvature, that one-half of the greater curvature, and that an inch at least of the duodenum should be removed; that all the "primary" glands at least should be taken (these are the lower and upper coronary, the right paracardial, the suprapyloric, the right suprapancreatic, the right gastro-epiploic upper and lower, and the retro-pyloric). The removal of all these parts is possible, and therefore the somewhat mournful view of the possibilities of the surgical treatment of cancer of the stomach taken by several writers are not justified. The difficulties to be encountered will chiefly lie in the removal of the right suprapancreatic glands, but that these difficulties are exaggerated is, I think, quite certain. In several cases I have, by using the "gauze stripping" method, removed the glands without any injury either to the hepatic artery or to the pancreas.

The following are the steps of the operation, as briefly outlined as possible:

1. The free opening of the abdomen in or near the middle line; the inspection of the parts; the packing of swabs around the area to be engaged in the operation so as to avoid any soiling of the parts. Nothing except the viscera at the moment engaged in the operation should be visible.

2. Preliminary ligation of the pyloric, gastro-duodenal, and left gastro-epiploic arteries (not the coronary), division of the gastro-hepatic omentum close to the liver.

3. Division of the duodenum between clamps, and the use, on the distal side, of a suture to close the duodenum by infolding. On the proximal side the exposed mucosa is well seared with the cautery, and a stitch taken round the clamp to prevent it slipping.

4. Ligation of the gastro-hepatic omentum below all glands in the greater curvature. The most important point is now to see that the middle colic artery is not wounded. The omentum is ligatured up to a point just beyond the middle of the greater curvature, so that all glands are removed.

5. The stomach is now turned well over to the left and the coronary artery ligatured at its origin from the coeliac axis. At once the lesser curvature is freed, and the stomach can be pulled lower. In this way all the coronary glands remain with the stomach.

6. Performance of posterior gastro-enterostomy. This is done before the stomach is cut away, being then far easier.

7. Division between clamps of the stomach from the oesophagus at its right margin to a point a little to the left of the middle of the greater curvature.

8. Cauterization of the exposed mucosa of the stomach and closure of the cut end of the stomach by a double suture.

9. Toilet of the peritoneum and closure of the parietal wound.

The size of the growth at or near the pylorus has no influence upon the extent of the resection. For the very smallest growth a resection to this extent is needed. If the growth invades the body of the stomach it may involve the removal of all of the stomach but the isolated area, after the manner described by me several years ago.

BRITISH MEDICAL JOURNAL, 1905, 1, p. 370. 2 *Annals of Surgery*, 1908, 1, p. 382.

A COMMUNICATION which has reached our hands records the aspirations formally expressed at the annual meeting on March 21st of a body entitled *l'Association médicale internationale pour aider à la suppression de la Guerre*. This, as we have mentioned on a previous occasion, is a peace society, claiming to be both international and medical, and having its head quarters at 25, Rue des Mathurins, Paris. The only "ven" of a novel character was a hope that the progress of science represented by aero-navigation will not be turned to the purposes of war.

ON THE SURGICAL TREATMENT OF GASTRIC ULCER, ITS COMPLICATIONS AND SEQUELAE.

WITH SIXTY ILLUSTRATIVE CASES.

By JOHN MARNOCH, M.A., M.B., C.M.ABERD.,
SURGEON TO, AND LECTURER ON CLINICAL SURGERY AT, THE
ABERDEEN ROYAL INFIRMARY.

Of all the advances in modern surgery none is more striking than that which has taken place in the treatment of gastric ulcer. Patients suffering from this disease, or some of its dire results, need no longer drag out the miserable existence they used, for surgery holds out every hope of restoring them to good health. During the last seven years it has been my lot to operate upon 60 cases of gastric ulcer, its complications or sequelae, and it is proposed in the present paper to give some account of them. The various conditions met with have been:

- (a) Active ulcer of the stomach, with and without adhesions to neighbouring viscera.
- (b) Cicatrized ulcer, with and without adhesions.
- (c) Hour-glass contraction of the stomach.
- (d) Subphrenic abscess.
- (e) Tumour after perforation of the stomach.
- (f) Perforating ulcer of the stomach.

The operative procedures adopted for the relief of the above-mentioned conditions may be divided into two main groups, namely, deliberate operations and emergency operations. They will be dealt with in this order.

A.—DELIBERATE OPERATIONS.

The deliberate operations have been:

- 1 case of ligation of ulcer.
- 1 case of pyloroplasty.
- 1 case of excision of ulcer and suture.
- 2 cases of drainage of subphrenic abscess.
- 1 laparotomy for tumour after perforation.
- 54 gastro-enterostomies, alone or combined with other operations.
- 1 case of gastro-gastrostomy.
- 1 case of lateral anastomosis.

The case of ligation of ulcer occurred among the earlier operations, and was performed on November 16th, 1901, in a young woman, 21 years of age, in whom an ulcer the size of a sixpence was found on the posterior wall of the stomach, at the extreme cardiac end, close to the lesser curvature. Here the ulcerated surface was invaginated by two layers of Lambert sutures, after which an opening was made in the anterior wall. The invaginated ulcer seized with forceps, pulled up, and a ligature applied beyond the base of the ulcer, the opening in the anterior wall being thereafter closed. The case did remarkably well and remained so for several years, after which she was lost sight of. On account of the awkward situation of the ulcer, the method of treatment mentioned was deemed safer than excision and suture.

In one case of cicatrized ulcer of the pylorus in a female patient, also one of the earlier cases, a pyloroplasty was performed. Here, although distinct improvement followed the operation, the result I am satisfied would have been better had gastro-jejunostomy been done.

In a male patient it was found that an ulcer the size of a two-shilling piece on the anterior wall of the stomach close to the greater curvature had contracted an adhesion to the abdominal wall well down in the left lumbar region. On breaking down the adhesions it was discovered that the ulcer had eaten through the stomach walls completely, its base being formed by the parietal peritoneum. In this case the margin was excised and the gap on the stomach wall sutured. On the completion of this operation, the stomach receded up into the abdomen and lay so naturally that no further operative procedure was deemed necessary. The operation was performed in January, 1905, and I believe the patient has had no further stomach trouble.

Two cases of subphrenic abscess following perforation of a gastric ulcer were met with. The first, a young married woman, was so bad when put upon the operating table that the administration of a general anaesthetic was out of the question, and the drainage, which was by the transplurular route, was under local anaesthesia. Although she caused grave anxiety for a few days, she ultimately recovered.

* Read at the November meeting of the Aberdeen Medico-Chirurgical Society.

after a tedious convalescence. The second case is interesting and worth giving in more detail.

Suppurative Abscess following Perforation of the Stomach: Operation: Rupture of Abscess into Colon: Recovery.

H. R., aged 25, was admitted to the Royal Infirmary on November 9th, 1905. A month previously she began to suffer pain in the left epigastric region. This continued fairly constantly until 1 a.m. on October 22nd, when she awoke with exacerbating pain in her left upper abdomen which soon spread all over and was accompanied for a few hours by sickness and vomiting. After a few days, during which the symptoms gradually subsided in severity, she began to progress satisfactorily, but four days previous to admission to hospital her temperature ran up and she again developed general abdominal distress. On admission her temperature was 102.5° F., pulse 123, respirations 23. There was acute tenderness and rigidity in the left epigastric and hypochondriac regions. Four days later this tenderness became less pronounced, but she complained of pain in her left shoulder and arm, extending down to the hand. By and by an area of dullness could be elicited in the left hypochondrium at the site of tenderness, and extending round into the left axilla.

Operation.

On November 18th a longitudinal incision was made over the dull area and deepened until pus was struck. This had an exceedingly offensive odour, was small in quantity, and lay in a cavity bounded behind and below by the stomach and transverse colon, above and in front by the abdominal wall, liver, and diaphragm. A drainage tube was lodged.

Evidently by the time operation was performed, the abscess had almost penetrated the wall of the colon; for, on the following night, about 4 oz. of pus were discharged per anum. The subsequent history is that pus discharged from the tube and at intervals from the rectum until December 17th, when it ceased. The tube track rapidly healed, and the patient made a speedy recovery.

Doubtless in this case Nature alone, unaided by operation, would have effected a cure, although more slowly. In another case, with a history of acute abdominal symptoms grafted on to a chronic stomach trouble, a tumour developed in the umbilical region. On opening the abdomen this was found to be a mass of plastic exudate binding down nearly the whole of the posterior wall of the stomach to the upper surface of the transverse mesocolon. The abdomen was closed, and the tumour mass gradually disappeared. Dyspeptic symptoms developed after her discharge from hospital, I believe, but so far she has not sought relief.

The most gratifying cases have been those in which gastro-jejunostomy has been performed. They were carefully selected, all, with one exception, having definite gastric lesions. These lesions consisted of ulcers unhealed and cicatrized, either non-adherent or having procured attachment to neighbouring viscera. While the vast majority have done exceedingly well, those cases in which the operation was performed for stenosis of the pylorus stand out pre-eminent among the good results. Patients suffering from this distressing sequela of gastric ulcer at once cease vomiting after gastro-jejunostomy, become perfectly comfortable and put on several stones of weight in a surprisingly short time. A typical illustration of the good results of gastro-jejunostomy in pyloric stenosis is the following:

Pyloric Stenosis: Dilatation of Stomach: Posterior Gastro-jejunostomy: Recovery.

J. P., aged 52, a scavenger, was admitted to the Aberdeen Royal Infirmary on June 17th, 1903, with a history of stomach trouble of ten years' duration. Briefly stated his symptoms had been: pain commencing in his lower dorsal region, radiating round his right side to his epigastrium, and vomiting. The quantity of vomited material was sometimes exceedingly large, and not infrequently he observed in it food taken the previous day. Also on occasions the vomitus was either very dark brown or black. All sorts of medical treatment had been tried, and eventually lavage had been carried out with only partial relief. He was a thin, sallow man, weighing 9 st. 3 lb. The evidences of dilatation of the stomach were pronounced, but no tumour could be palpated. The gastric contents contained free HCl.

Operation.

On opening the abdomen (June 20th, 1903), a hard, rounded tumour at least 1½ in. in diameter was found at the pylorus, almost completely obstructing the orifice. There were no enlarged lymph glands. A posterior gastro-jejunostomy was performed. After operation his vomiting ceased, he put on 2 st. in weight in a few weeks' time, and he is now, after a lapse of over five years, pursuing his work in perfect comfort, and asserts that he can "eat anything."

This case also well illustrates the tumour formation often found in gastric ulcer. In old-standing cases the growth is due to fibrous tissue developed during cicatriza-

tion, and is permanent, but in recent cases it is to be accounted for to a large extent, in some instances wholly, by oedema, and when this is so, it is remarkable how quickly and completely it disappears after invagination, etc. Doubtless, the cases of so-called malignant tumour which were published as disappearing after laparotomy, were merely instances of inflammatory induration. In the example just given no tumour could be palpated through the abdominal wall. Tumours of the pylorus, in my experience, often escape detection on palpation, and the explanation is that the gastro-hepatic omentum becomes involved in the inflammatory process, or in the cicatrization, so that it is shortened, and the pylorus with its tumour is dragged up under the shelter of the liver and costal arch, and so escapes detection through the abdominal wall.

Ulcerated stomachs are very prone to contract adhesions to adjacent viscera, but exceptionally they go further afield for their attachments, as in the case quoted above, where the cardiac end of the stomach was anchored to the abdominal wall in the left lumbar region. These adhesions are at once the safety and the distress of the patient. But for the timely attachment of the peritoneal covering over the ulcerated area the patient would not seldom be plunged into the disasters of perforation and peritonitis. As it is, while preventing this complication, these adhesions give rise to much pain and interference with the mobility of the stomach, with all its disagreeable consequences. The following are illustrative cases:

Gastric Ulcer adherent to Liver and Diaphragm: Gastro-jejunostomy: Recovery.

J. P., aged 23, a domestic servant, was admitted to the Royal Infirmary on June 10th, 1905, with a history of indigestion for seven years. Her symptoms had been epigastric pain, sickness, and vomiting. She was high coloured, fairly well nourished, and complained of great pain in the upper left epigastric region, where also there was distinct tenderness and possibly slight fullness on palpation. No sickness and vomiting took place during the period of observation prior to operation, but her pain was so persistent and so consistently referred to the same spot that it was decided to operate.

Operation.

On opening the abdomen (July 1st, 1905) through the left rectus muscle in the epigastrium, the anterior wall of the stomach opposite the middle of the lesser curvature was found adherent to the under surface of the liver, anterior edge of the diaphragm, and abdominal wall in the left epigastric region, by a dense irregular mass of adhesions. These, which were evidently the result of old ulceration, were severed and a posterior gastro-jejunostomy performed. There was hardly any post-operative sickness, and convalescence was quite rapid. Before leaving hospital she could take ordinary diet and had no pain. When last heard of she had continued well and was able to work.

Gastric Ulcer adherent to Pancreas: Posterior Gastro-jejunostomy: Recovery.

J. C., a cattleman, aged 58, was sent to the Aberdeen Royal Infirmary on November 14th, 1905, suffering from what was believed to be malignant disease of the stomach. Ten years previously he had had an attack of dyspepsia lasting six weeks. He continued well after this illness until March, 1905, when again he began to suffer from epigastric pain, at first continuously, but later with daily periods of remission. There was no vomiting, and the taking of food did not intensify his pain. On several occasions he noticed melæna. After having been continued to bed for four or five weeks he recovered, and was well again until September 17th following, when he had an attack of pain and vomited a quantity of blood. After that he was never quite free from pain, but vomiting was infrequent. He was very thin, weighing 9 st., and markedly cachectic looking. He referred his pain to the epigastric region, where there was distinct tenderness, especially over the right half and at the umbilicus. No tumour could be felt, and the other abdominal organs appeared normal. The gastric contents showed a trace of free HCl.

Operation.

On November 18th, 1905, the abdomen was opened through the right rectus muscle, and on the posterior wall of the stomach, rather nearer the cardiac end and about 2 in. from the lesser curvature, was an ulcer about the size of a shilling with indurated margins. The ulcer and adjacent walls of the stomach had procured a tight adhesion to the pancreas, but below there was sufficient room to perform a gastro-jejunostomy, which was accordingly done. There was little post-operative vomiting, and convalescence was smooth. The patient left hospital on December 29th, 1905, feeling very well, and put on flesh every week for some time afterwards. He has, I understand, remained well.

Gastric Ulcer adherent to Abdominal Wall and Costal Arch: Gastric Ulcer: Posterior Gastro-jejunostomy: Recovery.

Mrs. J. G., aged 48, who was admitted to the Aberdeen Royal Infirmary on August 1st, 1907, had had good health until two

years previously, since which time she had suffered at frequent intervals from discomfort and pain in the epigastrium, culminating in sickness and vomiting, half an hour after meals. The vomitus consisted of the food taken at the previous meal, but occasionally she brought up dark-brown material. There was no distinct history of melaena. For six weeks prior to admission all her symptoms had become aggravated, and she had lost flesh considerably. She was thin and pale, and complained of pain in the left epigastric and hypochondriac regions. There was distinct resistance in the regions mentioned, and on deep inspiration an ill-defined rounded mass could be felt. The vomit contained abundant HCl.

Operation.

On August 3rd, 1907, the epigastrium was opened through the left rectus, and the stomach found anchored by a broad mass of adhesions extending from the anterior wall at the cardiac end near the lesser curvature to the left costal margin and adjacent wall of the abdomen. A posterior gastro-jejunostomy was performed, after which the adhesions were severed from the costal arch and abdominal wall. These were found to surround a funnel-shaped cavity leading down into the stomach, and were evidently the result of active ulceration. The pyloric structures and the ulcerated edges of the gap in the stomach were clipped away, after which the organ was closed by two layers of suture. There was very little post-operative vomiting, and her progress towards complete recovery was quite smooth. She left the hospital on August 30th, 1907, and up to the time of writing has been quite well.

Other examples of cases with gastric adhesions, as well as with simple ulceration at the pyloric end of the stomach, might be quoted, but the above may be taken as typical of what is often found and the relief experienced after operation.

Two cases of hour-glass contraction of the stomach have been operated upon.

The first occurred in a female patient, aged 31, in whom the symptoms of pain and vomiting had been so frequent and distressing for a number of years as to render her quite unfit to work for most of the time. At the operation the stomach was found divided into two pouches—a small pyloric and a large cardiac. As it was quite apparent that stagnation was taking place in the cardiac pouch it was decided that an anastomosis between it and the jejunum would best meet the necessities of the case. This was accordingly done, and has been followed by a completely successful result, for the patient has not had the slightest trouble since operation, which was done two years ago, has put on weight, and looks a different person.

In the other case I regret having to record a fatal result from haemorrhage on the sixth day after operation. Here the patient was 63 years of age, much reduced by pain and vomiting, which had troubled her for years. On opening her abdomen the stomach was found constricted by dense cicatrization, dividing it into two pouches about the same size. The pylorus seemed free. A gastro-gastrostomy was performed, an ample opening being provided. She did well until the sixth day, when she showed signs of severe internal haemorrhage, rapidly sank, and died. Post-mortem examination showed the constriction to have been due to old ulceration, leaving a passage between the two pouches just sufficient to admit an ordinary lead pencil. The haemorrhage was found to have come from a non-malignant ulcer on the posterior wall of the cardiac pouch, close to the lesser curvature, about an inch from the constriction. The anastomosis was found quite tight, with no sign of leakage or peritonitis.

Remarks on Results and Treatment.

No more gratifying results are to be obtained in surgery than those which follow gastro-jejunostomy in properly selected cases; but it seems to be all too true that it is an operative procedure which has been much "overworked." To perform this operation on neurotic patients with vague and indefinite gastric symptoms is calculated to bring discredit on surgery, for instead of being productive of benefit it may, on the contrary, graft very real and serious disability on to what was mainly an imaginary trouble. Further, the more recent developments of gastric surgery show that gastro-jejunostomy must not be looked upon as a universal panacea for all benign lesions of the stomach, better results being got from other operative procedures according as the lesion is at or near the pylorus, and so obstructing the passage of food, or further away towards the cardiac end. In malignant disease of the stomach also, gastro-jejunostomy has a very doubtful place, unless combined with the radical operation of excision. It is, however, by no means always an easy matter to decide between a benign and malignant lesion, but the presence or absence of free HCl in the vomitus, although not entirely reliable, has been found decidedly helpful. As regards the result of the 42 deliberate operations, all have been exceedingly satisfactory except 5. Of these 5, 3 died, 2 from haemorrhage after operation, and 1 from regurgitant vomiting. One of

the cases of haemorrhage is quoted above, and occurred after gastro-gastrostomy for an hour-glass stomach; the other took place in the case of a woman, 63 years of age, on the sixth day after a posterior gastro-jejunostomy for extensive ulceration of the posterior wall of the stomach, the base of the ulcer being formed by the pancreas. The pathological report was to the effect that the ulceration was non-malignant. The interest of these two cases lies mainly in the fact that fatal haemorrhage from a benign ulcer may follow operative interference even though the anastomotic openings are ample, as they certainly were in these cases, and although no mechanical appliance is employed. The death from regurgitant vomiting occurred on the eleventh day after posterior gastro-jejunostomy. Here the mesenteric side of the jejunum had become adherent to the opening in the stomach, dividing it into two, a small efferent and a large afferent opening. Thus kinking had occurred, and once more goes to prove that regurgitant vomiting is due to a mechanical obstruction at the efferent opening. In this connexion another case which came under my care in 1902 on account of regurgitant vomiting may be mentioned.

He had had an anterior gastro-jejunostomy performed in 1897 for a stenosis of the pylorus, but had been much troubled with vomiting of bilious material since the operation. His vomiting generally took place from half to three quarters of an hour after food. I found that the proximal loop was short, and ascended to the stomach almost vertically, while the distal loop likewise left the anastomosis, which by the way was quite large, in a vertical direction. A lateral anastomosis between the loops was performed, and for several months he did well. The vomiting again returned, however, and he seemed to be almost as bad as ever. Curiously enough, after persisting for a considerable period it ceased, and he has remained well for several years.

In another case, of a woman aged 27, who for eleven years had suffered from pain, sickness, and vomiting, and in whom a puckered pylorus with dilatation of the stomach was found, a posterior gastro-jejunostomy was done. The vomiting still goes on, but the pain she suffered from is relieved.

Lastly, at the urgent request of a highly neurotic patient with some dilatation of the stomach and complaint of "heavy feeling" after meals and who had been advised by an eminent physician to have a gastro-jejunostomy performed for his trouble, I did the operation. No definite lesion to account for the dilatation could be found, and the procedure, although it did not aggravate the neurosis, led to no improvement.

With one exception all the gastro-jejunostomies have been posterior. In none of these was a proximal loop left, but in the earlier cases the jejunum was not drawn quite so tightly towards its anastomosis. The site selected in the stomach has been always the most dependent part and as close to the greater curvature as possible. As the greater curvature of the stomach at its most dependent part runs often quite horizontal for a short distance, the part of this horizontal portion nearest the duodeno-jejunal junction—that is, towards the left, has been selected. This permits the anastomosed jejunum to maintain its natural direction—namely, vertically, or almost vertically, downwards. Moreover, mutual dragging, and therefore possible kinking, is obviated. Where the distal portion of the intestine after anastomosis seemed to turn more to one side than another, a supporting suture was always inserted so as to preserve this direction, also with the same object in view, that of avoiding kinking. Such supporting sutures seem to me to be essential when the anterior operation is performed. It is important also during the suturing not to embrace too much of the jejunal wall, otherwise the bowel is apt to become flattened against the opening in the stomach and the occurrence of vicious circle favoured.

B.—EMERGENCY OPERATIONS.

There are few intra-abdominal emergencies that appear with more startling suddenness than perforation of the stomach. It hurls its victim with a tragic swiftness from comparatively good health into a position of the greatest peril. Nor is its guise always certain, for although in the majority of cases it produces a clinical picture once seen never to be forgotten, in a certain number it simulates other abdominal disasters. The death roll from perforation must be enormous. Although Mikulicz was the first to suture a ruptured ulcer in 1880, it was not till 1892 that the operation was accomplished successfully by Kriege. Once the closing of a perforation was demonstrated to be a feasible procedure, many cases have been operated upon and many successful results published. In order to arrive at an estimate of the mortality after suture of perforated

ulcer, several investigators have collected large numbers of published cases, and drawn conclusions therefrom. But it is more than doubtful if these conclusions are to be relied upon, for the tendency has been to publish successful cases, while many unsuccessful ones are not heard of. The percentage of recoveries, therefore, in these collected cases is almost certainly too high. My own experience extends to all 18 cases, which are appended in tabular form. The first occurred in March, 1902, and the eighteenth in March, 1908. They are given in chronological order.

Table of Operations for Perforation of the Stomach.

	Sex.	Age.	Duration.	Situation.	Result.
1	F.	17	18 hours	Prepyloric	D.
2	M.	45	28 "	Prepyloric	D.
3	F.	19	4 "	Cardiac	R.
4	M.	33	30 "	Middle	D.
5	F.	28	9 "	Prepyloric	D.
6	M.	28	20 "	Prepyloric	D.
7	F.	19	23 "	Middle	D.
8	F.	39	8 "	Cardiac	R.
9	F.	46	3 "	Prepyloric	D.
10	F.	24	12 "	Cardiac	D.
11	F.	19	29 "	Prepyloric	R.
12	M.	23	12 "	Prepyloric	R.
13	F.	24	8 "	Prepyloric	R.
14	F.	29	22 "	Prepyloric	D.
15	F.	25	20 ½ "	Pyloric	R.
16	F.	24	3 ½ "	Prepyloric	R.
17	M.	30	5 "	Pyloric	R.
18	F.	21	5 "	Pyloric	R.

* Posterior wall.

The percentage of recoveries among all cases works out at 50 per cent. exactly. If, however, they are divided into two groups—namely, those operated upon twelve hours or less after perforation and those over that time, the percentage of recoveries in the former is 70 per cent. and in the latter 25 per cent. Then, again, it will be observed that among the first 9 cases only 2 recovered, while among the second 9 cases 7 recovered. This is to be accounted for in various ways. In the first place, the average duration of the perforation in the first 9 cases is greater than in the second 9, and there has been a very distinct and steady improvement in the type of case sent for operation, especially latterly, as the advantages of early interference are becoming more and more recognized. A greater share of the credit in the reduction of the mortality must be given, I believe, to the improved technique which has been employed during the last few years in dealing with the acute abdomen. Rapid operating followed by the Fowler position and proctoclysis have done wonders in acute abdomens of all types.

Of the 18 cases, 14 were 30 years of age or under. Among the males the average age is 30, while among the females it is somewhat lower—namely, 26. Then, again, the proportion of females to males is 13 to 5, bearing out the well-known proneness of young females to acute ulcer of the stomach.

All the perforations with one exception were situated on the anterior wall of the stomach. No less than 10 of these were prepyloric, generally about 2 in. from the pylorus and midway between the two curvatures, while other 3 were actually on the pylorus itself. Of the remaining 5, 2 were on the middle of the organ and 3 at the cardiac end, the perforation on the posterior wall being among the latter.

Except in Case No. 1, in which the perforation was ragged and irregular, all the ruptures have presented the characteristic clean-cut, punched-out appearance, and have varied in size from the head of a pin to a large split pea. Round the opening a variable amount of induration has been the rule, with friability of the tissues

—a friability which increases with the duration of the perforation. In one or two an ineffectual attempt to wall off the rupture by adhesions has been observed.

Symptoms, Diagnosis, and Treatment.

A study of the symptoms of these 18 cases brings out many points of interest. First of all, as regards previous history, 17 had chronic indigestion, the symptoms of which, however, were not always characteristic of ulcer. Only occasionally did one get a definite history of hæmatemesis. In 8 there was distinct aggravation of the pain prior to rupture. This period of aggravation varied in duration from three weeks to one hour, the average being about twenty-four hours. In one or two cases the symptoms seemed to have been entirely in abeyance, the patients apparently being in perfect health when perforation occurred. In Case No. 17 no chronic history of indigestion was present at all. His case is as follows:

Perforation of Gastric Ulcer: Operation Five Hours Afterwards: Recovery.

G. G., aged 30, a carter, had had absolutely no illness until January 12th, 1908, when he began to suffer from abdominal pain in the epigastric and right iliac regions. For three days this continued, and rendered him unfit to work, but it then subsided, and he resumed his occupation. Two days later, at 10 p.m., the pain recurred suddenly, and with such intensity as to cause him to roll about and groan with agony. The pain was felt sometimes in the epigastrium, sometimes over the area of the appendix. He was sent to the Aberdeen Royal Infirmary. When seen there, he lay on his back with his knees drawn up, and cried out with pain. His temperature was 96.4° F., pulse 80. Respirations 36, shallow and thoracic in type, the abdomen being quite still. The rigidity of the abdominal muscles was general, but most pronounced over the right half of the abdomen. Acute tenderness was present both in the right epigastric and iliac regions, more particularly the latter. The liver dulness was present and the flanks were resonant.

Operation.

Five hours after perforation the abdomen was opened over the appendix, and a quantity of thin, inodorous purulent material escaped, but the appendix itself seemed perfectly normal. The stomach was then explored through a central epigastric incision, and a quantity of gas and fluid escaped. A round, punched-out-like perforation, the size of a split pea, was easily found, situated exactly over the anterior aspect of the pylorus. This was invaginated, and closed by two layers of Lembert suture. A Keith's drain was lodged in the pelvis through a suprapubic incision, and then the abdomen flushed from the upper wound downwards, the saline solution carrying the purulent fluid with particles of food out at the Keith drain. He was propped up into the semi-sitting posture in bed, and his convalescence never caused anxiety.

The entire absence of gastric symptoms until five days before perforation in this case is certainly remarkable, more especially considering the situation of the ulcer. It is difficult to believe that the ulceration had not existed for some time in spite of the entire absence of symptoms.

The pain of a ruptured ulcer, as one would expect, is referred most often to the epigastrium. In 3 of my cases it was confined to this region, while in 5 others it radiated, in addition to (a) the lower part of the sternum and ribs, (b) between the scapulae, (c) the lower costal margin, (d) and (e) appendical area. In 5 cases pain was complained of away from the epigastrium, being referred to (a) the lower abdomen, back, and shoulders, (b) umbilical region, (c) appendical area, left shoulder, and arm, (d) and (e) appendical area. Thus it will be observed that in 5 out of the 18 cases the area of the appendix was implicated either in conjunction with other regions or alone. When the upper abdomen and the appendical region were both involved, it was found on careful inquiry that the pain began above first and then gravitated downwards to the right. The explanation which has been put forward of this is probably the correct one—namely, that when rupture takes place the extravasation is at first confined to the site of the perforation, and pain is referred there; but in the course of an hour or two, guided by the colon, the stomach contents, etc., track downwards to the right iliac fossa, carrying infection and inflammation to the peritoneum of that neighbourhood, with attendant pain. Why the pain of a perforation should from the beginning be referred to the right iliac region, as it was in 2 of my cases, is difficult to understand. In the following case (No. 5) the pain both prior to and after rupture was referred to this part of the abdomen.

Perforation of Gastric Ulcer: Operation Nine Hours Afterwards: Death on the Fourteenth Day from Pneumonia.

Mrs. K. E., aged 28, with a very indefinite history of several attacks of indigestion consisting of epigastric pain occurring about two hours after food, and accompanied by vomiting, but no hæmatemesis, was seized on November 29th, 1903, with pain over the region of the appendix. This pain remained of moderate severity until 2 p.m. on December 2nd, when suddenly it became intense, and she had to take to bed. Soon the pain radiated from the right iliac fossa over the rest of the abdomen, and she vomited several times, but no blood was observed in the vomitus. When admitted to the infirmary she looked pale and collapsed, her pulse was 123, temperature 38.4, respirations 36. There was general abdominal rigidity and tenderness, but the latter was most pronounced in the right iliac region.

Operation.

Nine hours after the sudden aggravation of the pain, the abdomen was opened over the appendix, and immediately there escaped a quantity of thin purulent fluid. The caecum and appendix were red and congested, and had small patches of exudate upon them. The appendix was rapidly removed, but it became evident on closer examination that it was not the offending organ—a conclusion confirmed by the inodorous nature of the pus. Immediate incision was therefore made in the epigastrium, and at once a circular punched-out-like perforation, about 2 1/2 in. in diameter, revealed itself on the anterior wall of the stomach near the pylorus, and equidistant from the greater and lesser curvatures. The area around the opening was cleansed and irrigated by two layers of Lambert suture. The abdomen was flushed, and then closed with drainage. Although the respirations continued fast she did well until December 7th, when signs of pneumonia developed over the left base. From this condition she never recovered, and died on December 14th, thirteen days after operation.

Vomiting, never a marked feature after perforation, was absent altogether in about a third of my cases. When it does occur, the presence of very minute particles of blood clot may occasionally be detected on minute inspection of the vomitus.

It is too widely believed that absence of the liver dullness is an early symptom of perforation. This is not so, for in every one of the above cases which was sent for operation before the rigidity of the abdominal muscles had begun to pass off liver dullness was found. In some it was diminished, while in others it was unaltered. So long as this protective muscular rigidity lasts, in some cases for many hours, the extravasation of air is more or less held in check, and the liver dullness is not obliterated. Later, with the spreading peritonitis, muscular relaxation, and commencing distension, the dullness vanishes, a sign that Nature is losing its power of resistance, and the patient is passing into the final stage of the disease.

Another point that perforative peritonitis teaches, and that is that a certain amount of fluid in the abdominal cavity is compatible with resonant flanks. Completely dull flanks, like the absence of liver dullness, is a sign of advanced peritonitis. In the earlier stages the fluid in the peritoneal cavity, moderate in amount and limited as it often is by adhesive peritonitis, fails to reach the flanks, or does so only to a small extent, and consequently the colon resonance is not interfered with or only slightly diminished.

The only disease with which perforation of the stomach was confounded in my cases was appendicitis. In 4 the appendix was explored in the first instance. In 2 of these, from the fact that the pain and tenderness were most acute over that region, a diagnosis of appendicitis was made, while in the other 2 it was found impossible prior to operation to differentiate between a rupture of the stomach and a perforated appendix. In arriving at a conclusion, too much stress cannot be laid upon the previous history. A chronic history of ill-defined dyspeptic symptoms preceding an acute abdominal crisis should always lead one to suspect the rupture of an ulcer. Then, again, I believe the pain of a perforation is more agonizing than that of a ruptured appendix. When pain is referred by the patient equally to the epigastrium and right iliac region, a good guide to the site of the lesion is, which of the two regions is the more tender. When the diagnosis is uncertain and the abdomen is opened over the appendix the odour of the purulent fluid is, I believe, of great diagnostic value. The appendix may share the general peritonitis and show patches of septic exudate and it may occasionally be difficult to decide from its appearance whether it is diseased or not, but if the pus is inodorous the stomach ought at once to be explored. The offensive odour of the pus in a case of ruptured appendix is rarely

absent, while in rupture of the stomach there is little or no odour.

As in all other acute abdominal cases, the earlier operation is undertaken the better the prognosis. This is well borne out in the table given, the mortality among those got within the first twelve hours being much less than among those got at a later period. But while the duration of the perforation is of chief importance, there are other considerations which have a bearing on the prognosis, namely, the amount and character of the food in the stomach at the time of rupture, the size of the perforation, the extent of the extravasation, and last, but by no means to be neglected, the resistance of the patient. As showing how the amount of extravasation may be limited, the following case may be quoted:

Perforation of Gastric Ulcer: Operation Eight Hours Afterwards: Recovery.

J. M., aged 24, a domestic servant, had for several years suffered from anaemia and frequent attacks of pain and vomiting about an hour after meals. She had never had hæmatemesis. For twenty-four hours prior to perforation she had more epigastric pain than usual, but it varied in severity until 1 p.m. on March 26th, 1906, when it became suddenly very intense and she had to go to bed. The pain now radiated through to the lower dorsal region and up to the left shoulder, and was accompanied by vomiting of a light brown material. Her physician ordered her to hospital, where her condition was found as follows: General appearance good, temperature 101 F., pulse fair in quality, 106, respirations 30. She complained of pain in the left epigastric and lower dorsal regions and over her left shoulder; abdominal respiration absent. Tenderness in the left epigastrium was most pronounced, and there was cutaneous hyperaesthesia in Head's triangle. The abdominal muscles were very rigid, especially the recti at their upper part. Percussion note all over the abdomen, including the flanks, was clear, and the liver dullness was not diminished.

Operation.

At 9.20 p.m. on March 26th, 1906, eight hours after perforation, the abdomen was opened in the epigastrium through the left rectus muscle; a small quantity of turbid fluid escaped, and on exploring the stomach a perforation was revealed on the anterior wall, 1 in. from the lesser curvature and 2 in. from the pylorus. This perforation was almost occluded by a small finger-like process from the gastro-hepatic omentum and by a partial recent adhesion of the ulcerated area to the diaphragm and edge of the liver, so that an opening only the size of a pin-head was left uncovered. On separating the light adhesions and lifting off the finger of omentum the full extent of the perforation became evident. It measured 3/4 in. in length by 3/8 in. broad, and its edges were clean cut. Round this opening was a small quantity of turbid fluid. After the surrounding area had been wiped clean, the ulcer, which was about the size of a shilling, with indurated edges, was irrigated by two rows of Lambert suture. The anterior surface of the stomach and upper surface of the transverse colon were wiped with normal saline solution, and as the rest of the abdominal cavity was apparently uncontaminated, the abdominal wound was closed without drainage. The patient made a completely smooth recovery, and was discharged well on April 23rd, 1906.

But for the purposeful-like action of the finger of omentum and the limiting adhesions of the ulcerated surface, this patient's condition would have been much worse. Later complications also may vitiate results which are immediately successful. Of the 10 cases which were operated upon twelve hours or less after operation, 3 died. These 3 recovered from the immediate effects of the operation, dying later of complications: Case No. 5, which is given in detail above, succumbed fourteen days afterwards to pneumonia, Case No. 9 twenty-seven days later to acute mental symptoms, Case No. 10 nine weeks later to pyaemia.

The treatment of perforation of the stomach resolves itself into the treatment of the peritonitis after removing its cause. The closure of the rupture can be effected either by two rows of Lambert suture or a purse-string overlapped by a Lambert suture. It is safer, I believe, to employ two layers of sutures, especially in late cases, where the affected area is oedematous and friable, and sutures are exceedingly apt to tear through. As a rule, it is not a difficult matter to find a perforation, but occasionally, as the following case shows, it is an impossibility, and then other methods of treatment must be resorted to.

Perforation of Gastric Ulcer: Operation Twenty-nine Hours Afterwards: Gastro-cutaneous Fistula: Recovery.

G. C. aged 19, a domestic servant, had a history of pain or discomfort after meals for an indefinite period. In May, 1905, she had an attack of rather severe abdominal pain, which incapacitated her for work, and one milder attack a little later. On November 23rd, 1905, at 4 p.m., she felt sick and vomited, and immediately afterwards was seized with very intense

abdominal pain in her right iliac region, left shoulder and arm. This pain diminished after a couple of hours but later again increased in severity. Pain remained agonizing during the night and extended from the right iliac fossa all over the abdomen. No vomiting occurred after the onset of severe pain. She was admitted to hospital at 8 p.m. on November 24th, 1905, when her condition was as follows: Temperature 38.8, pulse 120, respirations 35. Her appearance was good; she complained of general abdominal pain but most severe about the umbilicus. Abdominal respiration was fair over the upper half which was also somewhat retracted, less marked over the lower half which was rather distended. Abdominal tenderness was general, but most pronounced just above the umbilicus. The liver dullness was normal.

Operation.

In view of the pain having been first felt in the right iliac fossa, the abdomen was opened, twenty-nine hours after the commencement of the acute illness, over the appendix. This appeared normal. Immediate epigastric incision was then made and the anterior wall of the stomach was found drawn up and adherent to the under surface of the liver by patches of recent yellow exudate through the interstices of which was escaping turbid fluid containing numerous food particles. These adhesions were broken down by a search instituted for the perforation, but it completely defied detection. The turbid fluid came welling up from the pyloric end of the stomach, and this, combined with the patches of lymph on the stomach wall, so effectually obscured the field that the search, which could not be prolonged on account of the fact that the patient's pulse and general condition were rapidly running downhill, had to be abandoned. The whole area of the stomach affected was therefore packed over with sterile gauze, the end of which was brought out at the upper angle of the abdominal wound. This was then closed after the peritoneal cavity, the soiling of which was partial, had been wiped clean.

For the first three days the dressings had to be frequently changed, on account of a greenish saecage. At the end of this time, under an anaesthetic, the gauze tampon over the stomach was removed with difficulty. No sooner had the last of it left the wound than 6 to 8 oz. of bile-stained fluid, containing small masses of curdled milk and glairy mucus, escaped. No subsequent plugging was used, and for an hour and a half after removal of the tampon she complained of pain in the left shoulder. At first the saecage from the wound was considerable, but the abdomen remained perfectly quiet, and she soon expressed herself as comfortable. For six days she was fed per rectum, but after this minute quantities of milk and water were administered by the mouth and gradually increased. Some of the curdled milk appeared at intervals in the discharge from the epigastric fistula, but gradually the quantity diminished, and discharge ceased on December 15th, three weeks after operation. She was dismissed, able to take ordinary diet, on February 2nd, 1906.

In dealing with the resulting peritonitis my earlier practice in perforation cases was to flush the abdomen regularly; but latterly this procedure has been abandoned, wiping alone being employed, except in widespread soiling. In extensive extravasation where fluid and food particles have got well below the transverse colon, then flushing with sterile salt solution is still employed in the following manner: A stab wound is made above the pubes and a Keith's drain lodged in Douglas's pouch. The sterilized end of the rubber tube from the irrigator, the glass nozzle having been previously detached, is then, guided by the hand, introduced through the epigastric incision into the abdominal cavity, which is then flushed from above downwards, the fluid emerging through the Keith's drain. This is carried out, the flexible tube being moved about to special pockets, until the fluid from the drain comes away clear, after which the epigastric incision is closed, with or without drainage according to circumstances. It is of paramount importance that the irrigating fluid should be of a proper temperature, otherwise shock will certainly be induced. The Fowler position and proctoclysis have so revolutionized the outlook in the acute abdomen, and have met with such wide acceptance, that no further comment need be made on this excellent method of after-treatment.

The routine performance of gastro-jejunostomy, at the same time as the perforation is dealt with, has been recently advocated with plausible but by no means convincing arguments. The aim of operation on a perforation is to avert death, and I feel convinced that the additional time necessary to make the short circuit will turn the scale against many cases requiring every particle of strength to stand even a short operation. The more rapidly the perforation and peritonitis can be dealt with compatible with efficiency the better the chance of recovery; and to lay it down that the performance of gastro-jejunostomy is an essential part of the treatment of a perforation seems to me fraught with the greatest danger. True, in certain early cases, gastro-jejunostomy may be

added to the operative treatment with safety and advantage, but it should be employed with the greatest discretion. An operation which is theoretically ideal and academic may be far from a life-saving one. Moreover, it seems now clear that gastro-jejunostomy should not be performed as a matter of routine even as a secondary operation, but should be reserved for those cases in which the perforation is so situated that its closure leads to pyloric obstruction or marked interference with the motor function of the stomach. That invagination and suture may lead to the disappearance of an ulcer is corroborated by Case No. 10, which died nine weeks after operation of pyaemia. At the post-mortem examination the pathologist could discover no trace whatever of the ulcer. So far two cases have come back with gastric symptoms after operation for perforation. In both the perforation was pyloric, and both have been relieved by gastro-jejunostomy.

In some of the cases recorded the patient was almost moribund when put on the table; but there ought never to be any question as to the propriety of operation—no matter how remote the chances of a successful result are, the patient ought to have the chance, for without operation the outcome is certain.

INTUSSUSCEPTION CONTAINING A SARCOMA OF THE INTESTINAL WALL: ENTER- ECTOMY: RECOVERY.

AND SOUTH HAMTS EYE AND EAR INFIRMARY.

AND

J. FORD PALSER, M.R.C.S., L.R.C.P.,

SOUTHSIDE.

THE following case presents some features so rare and interesting that we venture to consider the notes worth publishing:

History.

E. S., a boy aged 4½ years, was first seen at 9 p.m. on November 14th, 1908, when suffering from acute abdominal pain of a spasmodic character; between the spasms there seemed to be absolute freedom from pain—there was no vomiting, and nothing was to be felt in the abdomen; the attack lasted until 8 a.m. on November 15th. He was thin, pale and delicate-looking, and there was a previous history of abdominal pain and vomiting for two months, but otherwise he was quite well up to the time of this sudden attack.

On November 16th he was running about quite well.

On November 18th he had a similar attack, pain at intervals all day, vomiting frequently. Temperature, 100° F., pulse, 120. Nothing was felt in the abdomen. On November 19th the attacks of pain and vomiting continued; the temperature was normal, the bowels constipated. No blood, but a little mucus was passed with hard faeces without straining. Retraction of both testicles was marked throughout the attack.

From November 20th to November 23rd the patient was much better, having pain only at times; vomiting had ceased.

On November 23rd a lump was felt for the first time to the right of the umbilicus; the following day he was better and no lump could be felt.

On November 24th, at 5 a.m., he had another severe attack of pain with vomiting which was more or less continuous; for the first time he showed signs of being seriously ill; he was pale with anxious expression, tongue and lips dry, pulse rapid and feeble; examination of the abdomen was difficult, and the right rectus abdominis muscle was very resistant; the pulse was 132, and the temperature 98.4°; a small constipated motion was passed during the day. The pain was very acute and of a spasmodic character, the boy being literally doubled up with it. As the result of a surgical consultation an exploratory operation was performed.

Under A.C.E. a well-marked sausage-shaped mass was felt to the right of the umbilicus, freely movable, well defined, of doughy consistence, and just above and to the median side was another smaller mass.

Operation.

On opening the abdomen through the right rectus abdominis muscle a congested enteric intussusception was found, about 4 in. or 5 in. in length, with a tightly constricted neck, close to which a mass of enlarged mesenteric lymphatic glands was present. As reduction was impossible, and the patient's condition extremely grave, the whole of the intussuscepted gut was resected as rapidly as possible, one of the mesenteric glands removed, and a speedy end-to-end anastomosis of the divided ends of the gut by suture was performed. The abdomen was then filled with hot saline lotion and closed by through-and-through silkworm gut sutures.

After-history.

The patient rallied well from the operation, repeated saline injections into the bowel being administered. There was an action of the bowels on November 29th, at 10 a.m., after injection, and the pain was greatly diminished. The temperature rose to 102° F. shortly after the operation; the pulse remained at or about 130. The tongue was for several days dry and red, and the patient continued very restless and irritable, and slept badly. There was no further vomiting. Small quantities of milk and water were administered by the mouth after the second day, and gradually the unfavourable symptoms subsided. On December 6th alternate stitches were removed, and on December 7th, as he continued restless and crying for his friends, he was allowed to go home. After that his progress was uninterrupted.

Description of Parts Removed.

On examination of the specimen, the neck of the intussusception was found to be very tightly constricted, the cause being a puckered indurated growth, rather larger than a shilling, situated laterally in the wall of the small intestine just beyond the neck of the intussusception, effectually preventing any attempt at reduction. The total length of the gut resected was about 18 in. when unravelled.

On microscopical examination the growth proved to be (according to the report of the Clinical Research Association) a large round-celled sarcoma. The report reads as follows: "The mass is a malignant new growth invading the muscle coat of the intestine. It is composed of large round cells in a delicate stroma with very thin-walled vessels. We conclude that it is a round-celled sarcoma."

The mesenteric lymphatic glands were too deeply placed to remove *in toto*, considering the serious condition of the patient, which precluded any lengthy operative procedures. Added to this they had all the appearances of being tuberculous, and malignancy was unsuspected; nor was the

growth discovered until subsequent examination of the resected intussusception; this alone prevented easy reduction, as the condition of the gut wall was merely that of congestion.

The patient is at the present time in fairly good health, though a resistance can be felt in the situation of the mesenteric glands, and his recovery has not been quite as perfect as one would expect in an ordinary case. His digestive functions remain good, but the ultimate prognosis one must consider very grave.

A NOTE UPON THE EMBRYOLOGICAL AND PATHOLOGICAL SIGNIFICANCE OF CERTAIN FOLDS IN THE ANAL CANAL.

By J. BERNARD DAWSON, M.B., B.S., F.R.C.S.,

YORK.

In a recent paper Dr. Arthur Keith, discussing the development of the proctodaeum, stated that—

In two cases, both females, the epithelium of the proctodaeum had budded out irregularly, so as to form diverticula, some of which projected for some distance into the perineal tissue, and undoubtedly correspond to certain diverticula which are found in the anal canal opening under the folds which join together the upper ends of the columns of Morgagni.

He is good enough to attribute to me the credit of pointing out these said diverticula.¹ I, however, have to thank Mr. F. C. Wallis, of Charing Cross Hospital, for having directed

my attention to the existence of these strange test-tube-like projections.² He attributes certain cases of rectal discomfort to the fact that these valvular folds uniting the upper end of the columns of Morgagni and the diverticula become inflamed and painful, the sinus doubtless acting as an efficient culture chamber for micro-organisms.

Mr. Keith was good enough to permit me to carry out some research work upon the subject in his laboratory.

Morgagni's original description of the anal canal gave little or no help. The most complete description of the anal canal is to be found in *Traité d'Anatomie Humaine* of J. J. Jonnesco and Charpey. Of the columns of Morgagni they say:

They have a triangular base below, which inclines to either side and is continued into the free border of the valves of Morgagni. The summit tapers off, and is lost in the rectal mucous membrane.

There is, therefore, no mention of any folds uniting the summit of the columns.

My work, under Mr. Keith's supervision, consisted of cutting sagittal sections through the pelves of some six fetuses of ages varying from 2 months to full time. Without exception, in every specimen the columns of Morgagni were united by folds of mucous membrane both above and below. In other words, the anal canal was surrounded by a series of depressions which were bounded above and below by valve-like flaps of mucosa and on either side by elevated ridges, which were the columns of Morgagni. One series of sections from a hydrocephalic female fetus of 6 months seemed to offer some clue to the solution of the problem. In this I was fortunate enough to find a distinct

Fig. 1.—A, Rectum; B, anal canal; C, remnant of proctodaeal membrane; D, vagina; E, bladder; F, cavity of uterus; G, peritonium; H, os pubis; I, ext. sphincter. Dotted lines indicate portion from which sections were cut.

remnant of the proctodaeal membrane; 6 mm. from the skin margin was a perforate septum across the lumen of the anal canal forming a circular shelf, of varying width, around the bowel; it was clearly an imperfect proctodaeal membrane, which had persisted in a fetus that, save for the hydrocephaly, was perfect.

Had the septum been complete the condition would have been one of imperforate anus, in which the rectum ended blindly at the site of a fully-developed proctodaeum.

Below this imperfect rectal septum the anal canal was perfect, the columns and lower valves of Morgagni being well developed, the upper ends of the columns, however, disappearing under the membranous remnant. On microscopical examination it was seen that above the mucosa of the rectum was of the usual type, below the stratified epithelium of the anal canal is found. The septal shelf itself had different coverings above and below—the upper or rectal surface being clothed with the usual columnar rectal mucous membrane, exhibiting crypts and goblet cells, whilst the under or anal surface was covered with stratified epithelium. Between these two epithelia was fibrous tissue with a few muscular fibres, but no definite offspring from the regular muscle coats of the rectum. The circular muscular fibres of the rectum were aggregated to form the internal sphincter exactly at the level of the imperfect septum; below the circular muscular coat was continued, between the external sphincter and the anal submucosa, to the skin margin.

This fact is not easy to explain, for it is not easy to see why the internal muscular coat, a derivative of the splanchnic layer of the mesoblast, should come to occupy a position between epiblastic epithelium and the external

sphincter which is derived from the somatic layers of mesoblast. This downward continuation of the internal muscular coat of the rectum was present not only in my own sections, but also in some twenty sections lent me by Mr. Wood Jones. The longitudinal muscular coat and the external sphincter showed no variation from the usual description. One section showed that the depressions between the columns of Morgagni continued under the rectal shelf for some distance into the submucosa of the rectal wall, these diverticula being lined with stratified epithelium.

The conclusions which I have drawn from the above are as follows:

1. That there are commonly valve-like folds uniting the upper ends of the columns of Morgagni.
2. That these folds seem to represent remnants of the embryonic protodaeal membrane.
3. That the epithelium of the proctodaeum may be prolonged upwards, under these valves, into the rectal submucosa, and that these prolongations may persist as diverticula in the adult.
4. That where such diverticula are present it is an indication that the merging into one of rectum and proctodaeum has been imperfect to a greater or lesser extent.

The vertical measurement of the columns of Morgagni is marked by considerable variation, from 5 to 15 mm. being the average. It is known that the depth of the proctodaeum varies in like manner, so that it is reasonable to take the vertical measurement of the columns as some indication of the depth to which the proctodaeal

depression extended before it became continuous with the rectum.

The Pathological Significance of these upper valves and the sinuses beneath consists in:

1. The occurrence of inflammation in and around them produces symptoms of painful defaecation.
2. The possible part they may play in the formation of submucous fistula.
3. The possibility that the occurrence of inflammatory mischief at a spot where there is partially buried epithelium may originate carcinoma of the squamous variety, such as is found in the anal canal.

TREATMENT OF "PORT WINE" STAIN.

I READ in the BRITISH MEDICAL JOURNAL of February 6th, in the paper on radium, by Sir Frederick Treves, the following:

It can cure "port wine" stain, and I would ask surgeons at the present day what measure they have available of which they can say the same.

In answer to this I would say that, in my opinion, the most successful method of treating such at the present day is by the x rays. It is five years since I first used this method for a "port wine" stain involving almost the half of the

face. The patient was shown at a meeting of the Glasgow Northern Medical Society. The result was extremely good, and was produced without noticeable scar. Since then I have been using the same method in other similar cases, and have found no method equal to it.

Glasgow.

JOHN DONALD.

RADIUM IN LUPUS ERYTHEMATOSUS.

THE great interest which has been aroused by the treatment of lupus erythematosus by radium has induced me to send you photographs and brief particulars of a case in which that remedy has been successfully used.

D. M., a girl aged 11 years, with tuberculous history on mother's side, was attacked by lupus on the bridge of the

Fig. 1.

nose in September, 1906. After undergoing treatment elsewhere, she came as an out-patient to the Chesterfield and North Derbyshire Hospital, and the x rays were applied. The disease was arrested, and eventually the part healed, with some loss of substance and consequent disfigurement. Whilst the nose was being treated, a second outbreak of the disease commenced a little to the inner side of the left leg, below the patella (Fig. 1). The x-ray treatment was applied, but this time unsuccessfully, and, as the disease

was spreading, it was thought advisable to send the patient to one of the London hospitals for the Finsen light treatment. As she would have had to wait a considerable time before admission, and the disease was rapidly increasing, I decided to try the effect of radium bromide, placed on a small disc and covered with mica. The ulcerated surface was covered with thin oiled silk, and the disc was moved slowly over the surface from twenty to thirty minutes, once or twice a week, as was thought requisite. The treatment was continued for a lengthened period, with the result as shown in the photograph.

MAMMARY CANCER RECURRING FOURTEEN YEARS AFTER OPERATION.

AFTER the address of Sir Hector C. Cameron, published in the JOURNAL of March 6th, the following notes of a case may be worth recording. In 1892 I persuaded a patient to go to the Royal Infirmary, Edinburgh, for operation. The left breast and all the lymph glands were

thoroughly removed. Her general health soon improved, and remained good till over two years ago. The disease appeared at both extremities of the old incision over the sternum and high up in the axilla, while the right well-developed breast remained quite healthy. The ulcer with its everted indurated edges and foul sanious discharge ate deeply into the tissues covering the sternum, and gradually, though slowly, extended upwards in the shape of a heart—apex downward—to the top of the breast bone. The skin over the trachea was affected, and frequent attacks of dyspnoea occurred. There was much stinging pain, with sleeplessness and emaciation. The sore in the axilla gave very little trouble, and for a wonderfully long time the right breast escaped. The poor woman was patient and resigned. All at once, however, the cancer, as if starved over the sternum, attacked ferociously the other breast, and quickly ate away from the sternal side a concave semicircle over the muscle beneath the gland.

The woman was now so weak, sallow, and emaciated that nothing further could be done, and she sank a few months ago, at the age of 64. In this case the woman was cheery and healthy for about fourteen years between the first and second attacks, instead of the two years we used to reckon upon.

The recurrence at the extremities of the primary line of excision points clearly to a residue from the first attack, and the attack on the other gland was very like a fresh and rapid outbreak of the disease, for there was no connexion between the dry, brittle sternum and the breast now attacked.

Kirkwall, N.B.

D. McNEILL, M.D.

ACUTE CEREBRAL PALSY IN A CHILD.

THE following case occurred recently in the Orphan Homes of Scotland, Bridge of Weir. It presented certain difficulties in diagnosis.

History.

A boy, aged 10, who had been a resident in the homes for four years, was admitted to the hospital on February 7th, 1909. For a fortnight previous to admission it was noticed that he had tremor, exaggerated on voluntary movement, and weakness in the lower limbs. There was also a history of his always having been dull mentally.

Condition on Admission.

The patient was well nourished; the face was rather flushed; Hutchinson's teeth were well marked; the pulse was slow (50), irregular, and intermittent; there was slight cough.

Nervous System.

Consciousness and memory were unimpaired. Speech was distinctly staccato. There was paresis of both lower limbs, the patient being unable to walk without support, and dragging both feet. There was volitional tremor of the upper limbs, which ceased when the patient was at rest; there was an oscillating movement of the head on attempted movement, and tremor in the tongue, but no muscular atrophy, and no apparent disturbance of the sensory functions. The knee-jerks were present, but not exaggerated; there was no ankle clonus; Babinski's sign was elicited; the reflexes in the upper limbs and the organic reflexes were normal. The pupils were equal and regular in outline, moderately dilated, and reacting sluggishly to light and accommodation. Lateral nystagmus was present. There were a few rhonchi in the upper lobe of the left lung; the spleen was not enlarged, and the other systems apparently normal.

A few hours after admission mental symptoms were noticed, such as occasional outbursts of laughter with no apparent cause, imagining brushes had been put in his bed, and attempting to get out of bed.

February 8th. There was no change in the condition, except that speech had become distinctly "slurring"; he had no difficulty in swallowing, and took nourishment well.

February 9th. His condition was much worse; there was pallor of the face; he appeared to be conscious, but was unable to speak, though he seemed to make attempts to do so when spoken to. He was unable to swallow, food

stuck between the cheek and gum, and saliva dribbled from the mouth. The features were immobile and mask-like, the mouth partly open, and the tongue protruded between the teeth. There was complete suppression of urine, and nothing was passed per rectum; he appeared to doze at intervals, and occasional jerky movements of the right arm and both lower limbs were noticed. The temperature was subnormal, and pulse 50. Some hours later there was rigidity of the left arm, which could not be fully extended, and both knee-jerks were lost. He gradually grew weaker, and expired at midnight.

Post-mortem Examination.

The brain was large and soft, and markedly congested, and numerous punctiform hæmorrhages were seen throughout the grey matter; there was no evidence of meningitis. Microscopic sections of the cerebral cortex (stained by the aniline-blue-black, Van Gieson, and Nissl methods) showed proliferation of neuroglia and thickening of the vessels. The nerve cells were markedly degenerated, and showed advanced chromatolysis. In some the cell outline was indistinct, the nucleus eccentric, absent, or in a few cases vacuolated; the processes, including the axis cylinder process, had sometimes entirely disappeared. The lungs showed numerous tuberculous nodules scattered throughout, most marked in the left lung; in the upper lobe of the latter was a fibrosed area. The mesenteric glands were enlarged.

The diagnosis evidently rests between disseminated sclerosis, acute ascending paralysis (Landry's disease), juvenile general paralysis of the insane, and cerebral syphilis. Before death the case presented features of bulbar paralysis, which was evidently the terminal cause of death. Attention may be drawn to the acute course of the illness—eighteen days.

Consumption Sanatoria of Scotland, Bridge of Weir.

THE DEVELOPMENT OF THE PARASITES OF ORIENTAL SORE IN CULTURES.

It may be of interest to some of your readers to hear that I have recently received from Dr. R. Row, Fort Bombay, two communications, accompanied by sketches and preparations, describing the successful culture of Wright's bodies (*Leishmania tropica*) from Oriental sore, and their development into flagellate forms.

When cultivated in human blood serum at the temperature of the laboratory (25° to 28° C.), Dr. Row found the parasites to increase in size and multiply by fission, so that the culture after forty-eight hours contains clumps and masses of relatively large, banana-shaped parasites, each having the macronucleus near the middle of the body, and the micronucleus near one end which is slightly blunter than the other. At or shortly after forty-eight hours a flagellum grows out from the micronucleus at the blunter end, and each parasite becomes a *Herpetomonas*-like organism, which swims actively by means of its flagellum, and becomes free from the clump. At seventy-two hours the culture consists of numerous such flagellate individuals, occurring singly or in pairs or small groups.

It is thus seen that the Wright's body of Oriental sore undergoes in cultures a development very similar to that discovered by Rogers in the case of the Leishman-Donovan body of kala-azar. There is, however, an interesting difference in the mode of cultivation necessary to obtain development, since Dr. Row was only able to cultivate Wright's bodies in human blood serum, and failed to obtain any development when the parasites were planted in sodium citrate. The difference in the reactions to cultural conditions of the two parasites indicates that their modes of transmission and development are also different.

This is, I believe, the first time that the parasites of Oriental sore have been successfully cultivated up to the flagellate stage. I have sent Dr. Row's paper, with illustrations, to the *Quarterly Journal of Microscopical Science*, where I hope it will shortly appear.

Reports of Societies.

SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

Friday, March 19th, 1909.

Sir PATRICK MANSON, K.C.M.G., President, in the Chair.
Kala-azar.

THE PRESIDENT showed a second case of apparent cure of kala-azar by injections of atoxyl. The patient, an officer in the Indian Army, who had been stationed on the North-West Frontier, fell ill in September, 1907, and in April, 1908, had all the clinical symptoms of kala-azar. Puncture of the liver revealed Leishman's organism after a considerable search. The patient was then put upon a course of atoxyl injections—3 grains every third day, soamin being afterwards substituted. There was little improvement for three months, but in August, for the first time in twelve months, the fever disappeared, and the patient gradually became quite well. Since then he had had no relapse, and was now apparently cured. *Post hoc, however, was not propter hoc*, and one or two cases did not justify absolute conclusions, but clinically the case was interesting and suggestive.

Work in the Philippines.

A summary of the work of a medical board which consisted of Major Ashburn and Captain C. F. Craig of the United States Army, embodying the chief results of their researches in the Philippines from March, 1906, to July, 1907, was read for Captain CRAIG. The writers stated that they considered they had obtained sufficient evidence to justify the differentiation of a new species of filaria indigenous to these islands. They based their conclusions on the fact that the embryos showed no periodicity, and that they were characterized by morphological features which distinguished them from those of *Filaria bancrofti*, and from all other filariae parasitic in man. *Filaria bancrofti*, however, as had recently been shown by Phelan and Nicholls, was, contrary to their original ideas, still the most common filaria in Manila, but these observers had also found one instance of infection by the parasite which it was now proposed to call *F. philippinensis*. Five cases of infection had been carefully studied by the writers, and in every instance it was found that there were practically the same number of filariae in the peripheral circulation during the day as at night. There was, in fact, nothing approaching periodicity, which had been always regarded as one of the essential characters of *F. bancrofti*. The morphological characters were also different, and the embryos possessed marked powers of progressive motion. Embryos also developed readily in mosquitos, but only in some species, *Culex fatigans* being the usual secondary host; they had not been able to obtain development in *Stegomyia*. A peculiarity to be noted about the ingestion of filariae by mosquitos was that a much larger number of embryos could be found in the stomach of the insects after feeding than were ever present in an equal quantity of peripheral blood; this apparent power of selection was difficult to explain. The time of development—until the metamorphosed embryo reached the labium of the mosquito and was ready for transmission to a new host—was fifteen days. With regard to the etiology of tropical dysentery, the results of their researches had been to confirm almost in every particular the work of Schaudinn; and they now regarded the differentiation of intestinal amoebae into pathogenic (*Entamoeba histolytica*) and non-pathogenic (*Entamoeba coli*) as fully proved. Infections by *Entamoeba coli* was extremely common in the Philippines, but that harmless parasite could be readily identified in the faeces and distinguished from its pathogenic relative without clinical observation. As to the etiology of dengue, the experiments of Graham, of Bayreuth, who showed that the disease was transmitted by mosquitos, were corroborated by experience gained in the Philippines. Both by filtered and unfiltered blood they had been able to transmit dengue from naturally infected soldiers to healthy men who volunteered for the experiment. There could be no doubt about the specific character of the infection, and they concluded that dengue was due to an ultramicroscopic organism (less than 4 μ) which could pass through a filter

that retained *Micrococcus melitensis*. They had also transmitted dengue by infected mosquitos, but their experiments were by no means always successful. Failure was probably due to the fact that a number of the men had already been infected during an epidemic of dengue, for it was shown that several of them were quite immune to the disease. Contagion could be absolutely inhibited by the use of mosquito curtains, and dengue could not be transmitted by fomites. Further inquiry into the etiology of rambosia had confirmed Castellani's views that the disease was caused by *Treponema pertenue*. That organism was morphologically indistinguishable from *T. pallidum*, and it had the same staining reactions. The average number of curves was eight, but as many as seventeen had been counted. In capillary tubes of serum *T. pertenue* remained alive for many days—in one instance thirty-four—and in these circumstances multiplication occurred by longitudinal fission. In tubes, agglutination was also a marked phenomenon. The commission had successfully inoculated five monkeys (*Cynomolgus philippinensis*) by serum from yaws tubercles taken from three different patients, and had recovered the treponema from all of the resultant lesions. Monkeys inoculated with heart blood and splenic juice did not develop yaws, nor did monkeys which had recovered from a previous attack of the disease. They had examined serum from many other varieties of tumour from many different sores, but they had found *T. pertenue* only in yaws.

Dr. G. C. Low said that, with reference to the filaria, there was much doubt as to how far it was justifiable to establish new species upon embryonic characters alone, although it was true that that had been done previously in the case of filaria. So far as he could see at present, insufficient evidence had been adduced by Captain Craig to justify the separation of *F. philippinensis* from *F. bancrofti*. The measurements were practically the same, the structure apparently identical, and progressive movements had possibly been due to the fact that the embryos had shed their sheaths. Nocturnal periodicity was not an essential specific character, and embryos of *F. bancrofti* were sometimes found in the peripheral blood during the day.

Mr. F. E. AUSTEN said that, with reference to the etiology of dengue, an epidemic fever which had recently appeared among the troops in the service of some of the Balkan States, and which was also prevalent in the Levant and in other places, had been asserted to result from the bite of an insect—*Phlebotomus papatasi*. This was a species of the large family of sand flies, and, so far as he could judge, the fever which it conveyed closely resembled dengue. Allied species of phlebotomus occurred in many of our own colonies. He had recently seen specimens from Timbuctoo and also from India, and it was probable that in the latter country a form of surra, which affected Tonga ponies, was conveyed by sand flies. Sand flies differed from mosquitos, in that they were much smaller, and that their cuticular coverings were hairs and not scales.

Sir PATRICK MANSON agreed with Dr. Low that more evidence was wanted to establish *F. philippinensis* as a new species. With regard to Entamoeba, Captain Craig's views appeared to be opposed to those of Musgrave, Strong, and other investigators who had worked in the Philippines, and the question of pathogenic function could not be regarded as finally settled.

Malta Fever.

Drs. G. C. LOW and ANDREW FOY read notes of cases of Malta fever which had been acquired in Northern Nigeria.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF PATHOLOGY.

Friday, March 12th, 1909.

A. R. PARSONS, M.D., F.R.C.P.I., President, in the Chair.

Polyserositis.

MR. W. I. DE C. WHEELER showed specimens from a man aged 34, sent from Galway with a large ascites. He was fairly healthy and had no other symptoms. Two years previously he had had his right pleura tapped, and when he came to hospital a small left pleural effusion was found

and tapped. The ascites increased in hospital. Ten days after admission the abdomen was opened. Covering the liver was a thick capsule, and over it there were little dips as if peas had been pressed into the surface of it. The liver was not cirrhotic. There were adhesions between the great omentum and the abdominal wall. The Rutina-Morison operation was performed. No sign of tubercle was found, and there was no growth of any kind. The operation seemed to relieve the ascites, and he lived eight weeks. He was only tapped once after it, and a very small quantity of fluid was found.

Dr. HARVEY said that on opening the abdomen only a small quantity of fluid was seen, but a considerable amount was afterwards found shut off by intestinal adhesions. The peritoneum covering the intestines was everywhere thickened, and in places an abundance of comparatively recent fibrin was matting the coils together. The liver was covered with a thick, opaque white capsule, in which irregular pits were seen, giving somewhat the appearance presented by snow on which drops of water are sprinkled. The surface of the spleen was somewhat similar. The cut surface of these organs was scarcely, if at all, abnormal. The spleen was perhaps a little tough but not at all markedly cirrhotic. The kidneys were normal in macroscopic appearance; their capsules stripped easily. The thoracic viscera were densely adherent to themselves and to the parietes. It was found possible after some time to isolate the left lung, which, in addition to general adhesions, was firmly attached to the diaphragm by a dense, finger-like process. The pleura was enormously thickened, and the whole organ when removed looked rather like an enlarged spleen. It was not possible to separate the heart and pericardium from the right lung. The pleura was not so extremely dense as that on the left side, and the right pleural cavity contained a considerable amount of fluid. The pericardium was greatly thickened, and closely adherent everywhere to the heart. On section it had a dense cartilaginous appearance. The heart was somewhat atrophic, the endocardium normal. Inoculations were made from the centrifuged fluid in the pleural and peritoneal sacs into four guinea-pigs, but without result. Microscopic sections showed the organs to be remarkably free from cirrhosis except immediately beneath the thickened capsules. The organs themselves were fairly normal but for congestion and some parenchymatous degeneration to be seen in the liver and kidneys. Part of the left lung near the pleural surface showed collapse with fibrosis, while portions of the right lung were emphysematous. The organs, with the exception of the above-mentioned changes, were healthy, while their serous coverings were immensely thickened, and such serous cavities of the body as were not totally obliterated were distended with fluid. There was absolutely no evidence of tuberculosis either in the sections or as a result of inoculations.

Dr. KILPATRICK said he had seen the patient during life, and thought the multiple serous effusions were probably the result of tuberculous infection. He saw him after the operation, and he was perfectly comfortable and better, then he suddenly died. Both the pathological finding and the clinical history were very remarkable.

Dr. MOOREHEAD said he had seen an almost identical case two and a half years ago. Such cases were of very considerable interest from their rarity.

Mr. WHEELER, in reply, said it had occurred to him that tertiary syphilis might explain the case, but there was no history of such.

Dr. HARVEY, in reply, said the remarkable thing was not why the man died, but how he lived. He had seen nothing so dense as the mass of adhesions in his thorax, and it was wonderful how the organs could move at all.

ROYAL SOCIETY OF MEDICINE.

OBSTETRICAL AND GYNAECOLOGICAL SECTION.

Thursday, March 11th, 1909.

HERRBERT R. SPENCER, M.D., President, in the Chair.

Pernicious Vomiting.

Dr. DRUMMOND MAXWELL gave an account of a fatal case of pernicious vomiting of pregnancy in a primigravida aged 26. Diagnosis was difficult, since the patient, after admission to hospital, ceased vomiting, and there was only the history of severe vomiting at home, unassociated,

however, with marked wasting. There was no characteristic alteration of the urine, and no albuminuria; the only ominous signs on admission were drowsiness and a very rapid, weak pulse; there was no jaundice. The patient passed successively through stages of restlessness, delirium, mania, and final coma. Autopsy revealed hyaline degeneration and necrosis of the central cells of the hepatic lobules, the kidneys also showing a severe parenchymatous nephritis. The diagnosis, uncertain during life, was based finally on the *post-mortem* appearances.

Ovarian Actinomycosis.

MESSRS. FRANK E. TAYLOR and WELBY E. FISHER, recorded a case which they claimed to be one of primary ovarian actinomycosis. Only six other cases of ovarian actinomycosis were on record, and in these the ovary had been infected by extension of the disease from some other locality. Professor R. F. C. LARRA said that the specimen shown was a good example of ovarian actinomycosis, but caution must be exercised before accepting the contention of the authors that the disease was primary in the ovary. Of the recorded cases of ovarian actinomycosis—a not inconsiderable number—there were some in which the evidence favouring a primary incidence of the disease in the ovary was very strong, sufficiently so to convince their observers of their authenticity. In the case under consideration, the clinical history, both before and since the operation, lent considerable support to the authors' contentions, but the actual relationships of the ovary to all the neighbouring tissues were not fully revealed. In a case which he had himself investigated, the ovary and part of the tube were affected. The rectal wall was thickened, and in the dense fibrous adhesions binding it to the ovary there were plentiful actinomycoses growth. Colonies were also found in the rectal wall and in the wall of the descending colon. His interpretation of this case, though still *sub judice*, placed the primary disease in the intestine, from which it had spread to the ovary, the intestinal lesions subsequently cicatrizing and healing. He ventured to suggest that a similar interpretation might be placed upon the present case. The speculation of the authors that the actinomycoses had entered the body by some hidden path without causing a local lesion, and had been carried to the ovary by the blood stream, was scarcely probable. One of the chief characteristics of this disease was the formation of a local lesion at or near the site of entrance, and a spread therefrom by direct continuity of tissue. Spread by the blood stream did take place, particularly the portal blood stream, but this was characteristically a late method of extension. Dr. T. G. WILSON remarked how difficult it was to be quite sure that a condition like actinomycosis was really primary in the ovary, and had not come originally from some part of the bowel, and described a case in point.

Primary Carcinoma of the Vagina.

Dr. HY. RUSSELL ANDREWS described the case of a multipara, aged 62, who had a carcinomatous ulcer, the size of a two-shilling piece, high up on the posterior vaginal wall. The cervix was free from carcinoma. The whole vagina was dissected out from below, and removed together with the uterus. At an early stage of the operation the vagina was converted into a closed bag by clamping with forceps bent at a right angle, with the object of preventing infection of the raw surfaces by carcinoma cells. The peritoneal cavity was closed by sutures, and the cavity between the rectum and urethra became obliterated. The patient was quite well when last seen, February, 1909, eighteen months after the operation. The President thought there was some advantage in the operation performed by Dr. Andrews, especially as there would appear to be less risk of the vagina tearing. Dr. F. J. McCANN said he had operated on a patient with primary cancer of the vagina by a different method to that mentioned by Dr. Andrews, and she was free from recurrence when last seen, four and a half years after the operation. He had seen five examples of primary cancer of the vagina. Dr. H. MACNIGHTON-JONES said that in view of the very few cases of primary carcinoma of the vagina recorded in British literature, he had sought for some statistics from abroad. From all these sources he had only been able to collect twenty-three instances of primary disease. In deciding the point of primary infection, it was absolutely necessary to exclude the portio and vulva. Dr. A. H. N.

LEWERS said he was surprised to find that some of those present considered this condition very rare. He had himself seen, speaking from memory, at least 15 or 20 cases of primary carcinoma of the vagina. In none of them, however, was the disease at a sufficiently early stage to induce him to attempt a radical operation, and he had therefore been obliged merely to scrape and cauterize the growth in such as had seemed to require some active treatment. Dr. RUSSELL ANDREWS, in reply, said that this was the only case of primary carcinoma of the vagina that he had seen. From what he had read he had considered that the condition was rare.

HARVEIAN SOCIETY OF LONDON.—At a meeting held on March 4th a discussion on the early diagnosis and treatment of *Cancer of the stomach* was opened by Dr. HALE WHITE and Mr. B. G. A. MOYNIRAN, whose papers are published at pp. 828 and 830. In the discussion which followed, Mr. D'ARCY POWER said his experience had been that hospital cases came for treatment in the late stages, and that private cases were unwilling to be treated for more than indigestion until hæmatemesis or secondary growths occurred. Carcinoma was nearly always secondary to chronic ulceration, developed slowly, and was localized for a considerable time to its point of origin. Secondary growths were unusual, and glandular enlargements in immediate neighbourhood might show no epithelial deposit. He had had no case under 30, and the majority of cases were between 50 and 70. Both sexes were affected equally. The symptoms were similar to those of chronic ulceration. No reliance could be placed upon the result of a single examination for free hydrochloric acid. A skiagraph after administration of bismuth had proved valuable in a case of advanced carcinoma; but his experience in early cases had shown that skiagraphs failed to reveal any thickening of the mucous membrane. Most reliance must be placed on an exploratory operation. If a thickening be found, a part should be removed and examined microscopically by a skilled pathologist whilst the abdomen was open. If the mass prove carcinomatous, a partial gastrectomy should be performed, together with a posterior gastro-entrostomy, an operation well borne by the patient. Irritation not only led to cancer, but increased the rapidity of growth. It was a mistake to allow a chronic ulceration of the stomach to continue indefinitely; a gastro-entrostomy should be performed in such cases, and thus produce anatomical rest. Further, in cases of carcinoma where complete removal was impossible a gastro-entrostomy would prevent further irritation. Dr. ROLLESTON said that very different pathological and clinical conditions were included under malignant disease of the stomach. Rare cases of diffuse lymphosarcoma, extending like a sheath along the alimentary canal, and possibly of infective origin, were obviously unsuited for the radical treatment of excision. The more ordinary forms of malignant disease fell into two main groups, which differed entirely in their clinical symptoms and as regards their possibility of cure by operation. The two groups were: (1) Carcinoma of the cardiac end, where the symptoms were mainly constitutional, namely, fever, anæmia, and debility, and suggested tuberculosis or infective endocarditis; (2) carcinoma of the pylorus, where the symptoms were mainly mechanical. As a subdivision of the second group might be included cases of carcinoma spreading from the pylorus and lesser curvature to the body of the stomach, and producing the leather bottle stomach. In Group 1 the growth was rapid, prone to necrose, to invade the left lobe of the liver, and set up diffuse suppuration on the adherent liver, a condition most unsuitable for operative measures. He quoted cases of carcinoma of the cardiac end of the stomach resembling pulmonary tuberculosis. One patient with fever and intestinal hæmorrhage brought up material containing acid-fast bacilli, but the necropsy revealed a gangrenous carcinoma containing acid-fast bacilli and no tuberculosis; the situation of the growth prevented vomiting. In another case a gangrenous carcinoma produced a subphrenic abscess, which in turn led to a left pleural effusion, which was the most obvious feature during life. In cases of carcinoma of the pyloric end, the diagnosis should be made before a tumour was palpable, for metastasis had occurred in many cases by this

time. In a patient with symptoms strongly suggesting gastric carcinoma, in whom a test meal shows an absence of hydrochloric acid in the gastric juice, exploratory laparotomy was justified to settle the question in the absence of tumour. It was important, when such an exploratory operation was undertaken, that the surgeon should, in the event of carcinoma being found without obvious metastasis, proceed to partial excision of the stomach, and not rest content with gastro-entrostomy. Mr. V. WARREN LOW said he had yet to learn how to make an early diagnosis in cancer of the stomach. He thought that a careful analysis of the symptoms, such as pain, increasing ill-health, etc., left a considerable degree of uncertainty in the individual case, especially in the class of case where the patient had suffered from stomach symptoms all his life. It was in every one's knowledge that constantly cases occurred where even the most experienced surgeons had been deceived at an operation by the similarity of an old ulcer to a malignant growth. He quoted a case in which in 1898 an anterior gastro-entrostomy was performed at St. Mary's for what appeared to every one to have been a hopeless case of stomach cancer. This patient was alive and well two or three years ago. As far as his experience had gone, he had learnt to rely very largely on the expert examination of the stomach contents. Dr. ARTHUR F. HERTZ attached great importance to two recent methods of examination in the early diagnosis of cancer of the stomach—namely, occult blood in the faeces and skiagraphy. Hæmorrhage from a gastric growth was rarely sufficient to give rise to obvious melaena, and blood was visible in the vomit in less than 40 per cent. of cases. Minute hæmorrhages were constantly occurring from the surface of every malignant ulcer, so that a small quantity of blood was constantly excreted in the faeces. Ewald first utilized this fact for diagnosis. Chemical tests were more satisfactory than microscopical or spectroscopic; the best were the guaiacum and the benzidine reactions made with ethereal extracts of stools after treatment with glacial acetic acid. Meat diet should be avoided for a few days prior to the first examination; 92 per cent. of 266 recorded cases gave a positive reaction. In no single case of gastritis, nervous dyspepsia, or pernicious anæmia had the test for occult blood in the stools been positive. In simple gastric or duodenal ulcer blood might be present in the stools, but always disappeared in two or three days under dietetic treatment. His experience with skiagraphy showed that information about the size of the stomach and the rate with which it got rid of its contents was not so reliable as that obtained by certain older methods of examination. Inflation of the stomach by carbon dioxide, produced by action of tartaric acid on sodium bicarbonate, gave constant results in sound individuals. Very slight dilatations could be readily recognized by this method. Traces of bismuth might remain in the stomach six hours after a bismuth meal sufficient to cause a shadow to x rays, and no evidence of pyloric obstruction was thus obtained. Traces of food residue, obtained by a tube at 3 a.m. after the last meal had been taken at 8 p.m., afforded almost conclusive evidence of organic stricture of the pylorus. After a bismuth breakfast x rays might show: (1) Obstruction at the cardiac end of the stomach, due to growth in this situation; (2) abnormality in the outline of the stomach caused by a projection of a growth into the lumen; (3) obliteration of the pyloric vestibule due to growth near the pylorus. Mr. CRISP ENGLISH said that the important early signs of cancer of the stomach should be given a more prominent place in textbooks on medicine and surgery; too much space was usually devoted to the classical signs, and patients suffering from the classical signs were usually in a hopeless condition. He referred to the difficulty which sometimes occurred during an operation in diagnosing a chronic ulcer from cancer, even after careful inspection through an opening in the stomach. If the possibility of a radical operation arises, the diagnosis must first be certain; his own practice in such cases had been to excise a portion of the diseased area for microscopical examination, and then to do a gastro-jejunostomy; if the excised portion proved malignant, a partial gastrectomy was performed later. He urged the more frequent performance of partial gastrectomy in preference to the palliative operation of gastro-jejunostomy.

SHEFFIELD MEDICO-SURGICAL SOCIETY.—At a meeting on March 4th, Mr. P. E. BARBER, President, in the chair, the following were among the cases shown:—Dr. G. WILLIAMSON: (1) *Partial Gastrectomy* and excision of about 10 in. of the transverse colon for carcinoma. About two-thirds of the stomach had been excised and posterior gastro-enterostomy performed. The transverse mesocolon was adherent to the posterior wall of the stomach and infiltrated with carcinoma. This necessitated resection of part of the transverse colon. The ends were closed by suture and lateral approximation performed. (2) *Double Frontal, ethmoid, and maxillary antral suppuration*, in which radical operations had been performed on all the sinuses. Submucous resection of the septum was performed to allow access to the left nostril. Dr. W. S. KERR: (1) A bilateral abductor *Paralysis of the vocal cords*. There was a feeling of fullness in the larynx externally and slight oedema of the arytenoid region. The inspiratory stridor was well marked. There was no dysphagia. The case was thought to be one of perichondritis of the cricoid. There was no disease of the chest or central nervous system. The case was improving under iodide of potash. (2) *Cases of Chronic maxillary sinusitis* treated by the radical operation. One was followed by a severe and extensive attack of erysipelas involving the face, scalp and neck. Slight oedema of the affected cheek still remained after six months. Dr. GILBERT MOULD, in a paper on the *Treatment of incipient insanity*, remarked that in spite of the diversity of mental diseases when fully developed there was at the commencement a great similarity of the symptoms. These included (1) changes in the circulation of the skin, loss of weight, loss of appetite, fetor of breath, constipation, amenorrhoea, and frequently headache; (2) excitement or depression, sleeplessness, alteration of character, alienation from friends and relatives, often bad dreams and noises in the head. The treatment of symptoms must not be neglected on the ground that they did not constitute the fundamental change, for in a disease of which so little was known it was quite rational to treat symptoms. As a rule patients were better treated away from home. Strict Weir Mitchell treatment was of limited utility; more recently rest in bed in the open air had been advocated. The old treatment of vigorous walking exercise gave good results in many cases. It did not follow that because a woman had broken down under the strain of tending a large family she required absolute rest in bed. It was sufficient in these cases that they had removed the strain. Nutrition was most important, administration of large quantities of milk being almost entitled to be regarded as a specific in the treatment of incipient insanity. Tobacco should be stopped, though there might be exceptions in the old. Most cases did better without tea. As small fluid intake meant irritability, plenty of fluid should be taken. Hypnotic suggestion in the hands of a gifted reputable practitioner might be of the utmost value. The greatest obstacle to the effective treatment of early insanity was the legal difficulties in the way of the medical man who wished to put his patient under proper care. Dr. GODFREY CARTER, in a paper on *Post-influenzal conditions simulating phthisis*, related four cases where following influenza there resulted a condition completely simulating phthisis. There was apical consolidation with well-marked signs associated with loss of weight, nocturnal temperatures of 100 and thereabouts, rapid pulse, but no tubercle bacilli in the sputum. All the cases recovered in the course of a few months, and the physical signs completely disappeared. In one case there was a large pleural effusion. Drs. F. WADY, G. SIMPSON, and A. E. BARFES joined in the discussion, and related cases where, following influenza, there had developed tuberculosis, and the bacilli had only been found after several examinations. Dr. CARTER, in reply, said that in his cases there had been such marked signs that if they were due to tuberculosis there would almost certainly have been bacilli in the sputum. Recovery was also so complete and rapid that tuberculosis was out of the question.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—At a meeting on March 12th, Dr. EDWARD SERGEANT, President, in the chair, a discussion upon *Amendments to the Midwives Act* was opened by Dr. KAYE. After giving some account of the conditions which were to be found in the West Riding prior to 1905, he referred to a large and

indefinite class of "handy women," who were ready to render assistance in any sort of illness among their neighbours, including confinements, with or without a doctor, payment being in money or in kind. In twenty-two sanitary districts in the West Riding there was no certificated midwife. In 1910 it would have to be decided what could be done for districts in which the work was at present being done by women who could not legally do it after that date. There would also be the probable failure of the supply of certificated midwives to fill the gaps made by the retirement or death of those now acting. After setting on one side as impracticable proposals that there should be a postponement of the penal sections of the Act, and that the handy women should be allowed special facilities for becoming enrolled, Dr. Kaye suggested that to meet the anticipated difficulties the Act should be so amended as to authorize local supervising authorities to grant to suitable uncertificated women a modified licence applicable only for a given period and within a well-defined area. The women so licensed should undertake to keep a list of the cases attended, and to observe certain primary rules. They should also be deprived of their licences in the event of a certificated midwife settling in the district. Drs. MCGRAVE, CRAVEN, and MEREDITH YOUNG were opposed to any proposal which had for its object the payment out of public funds of the cost of training midwives. Dr. BOWEN-JONES thought that the uncleanly habits of the handy woman was often the cause of serious mischief. Dr. TUBB THOMAS said that it was very difficult for a midwife to earn a living by her work in country districts. In Wiltshire there were probably not six who were doing so. He disapproved of establishing a second-hand set of midwives, and advocated the subsidising of county nursing associations. Dr. TEW considered that the demand for midwives would be met in good time, though if the rules were rigidly carried out a large number of those already on the roll would be struck off. Dr. MCCLEARY agreed that it would be most imprudent to postpone the carrying out of the Midwives Act at the proper time. If this were done a precedent would be set which might have most far-reaching results. Dr. F. E. CANE did not approve of the handy woman at all; he considered her a nuisance and an abomination. He also referred with dissatisfaction to the manner in which many women were trained as midwives. Dr. LYSTER said that, while the theoretical knowledge of their work had been so extended as to be almost farcical, the amount of practical knowledge was far too little. Dr. ARNOLD EVANS approved of subsidising existing nursing associations, and said that in Bradford the local authority gave to such an association £100 a year. The PRESIDENT said that he should be sorry to be connected with any supervising authority which had power to give secondary licences to untrained women. He looked forward with complacency to 1910 and did not anticipate there would be so much shortage in the supply of midwives as some people thought.

WEST LONDON MEDICO-SURGICAL SOCIETY.—At the meeting on March 5th Dr. E. FURNISS POTTER described the submucous operation for the removal of deviations and obstructive *Deformities of the nasal septum* as having revolutionized treatment in this direction. What were formerly regarded as purely ledge-like outgrowths of bone or cartilage were in reality the thickened angular summits of septal deflections, hence the sawing off of the obstructing spur was frequently disappointing, as only a small shaving was removed or else a large perforation made. In describing the technique of the operation the author laid stress on the necessity of cutting completely through the mucous and perichondrial coverings in order to ensure success in stripping the septum. If this were not done the elevator would be passed between the mucous and perichondrial layers, and considerable difficulties would be encountered. The operator should always make sure that enough bone and cartilage had been removed, otherwise the result was apt to be disappointing. Indications of sufficient removal were that the two mucous layers should hang plumb in the midline, and that the posterior wall of the pharynx should be easily visible. In conclusion, he claimed the following advantages for the operation: (1) The establishment with certainty of a free nasal passage, (2) no general anaesthetic necessary, (3) rapid healing, no splints or troublesome after-treatment needed.

Reviews.

DISEASES OF THE STOMACH.

THERE could not be a better account of the operative indications in diseases of the stomach than that recently published by Dr. A. DELANGRE,¹ who follows closely upon the lines laid down by Hartmann and Terrier. In his historical review of the development of stomach surgery he credits Mr. Moynihan to America, while "Macdonald" is included amongst distinguished British surgeons. The first part discusses the treatment of malignant diseases of the stomach in which the desirability of early operation and early diagnosis is urged, but nothing is added to our all-too-scanty knowledge on the subject. He considers that surgeons are somewhat prone to talk too optimistically about the cures that would result if cases were sent to them for operation earlier; he maintains that of reputed cures counted in surgical statistics, even among the cases in which early and complete removal was possible, those which have remained free from recurrence for three years do not constitute more than a third of the total. Without wishing to weaken the case for early diagnosis, and while advocating liberal recognition by the profession of the beneficial possibilities of surgical interference in cases of suspected cancer after the means of medical diagnosis have been exhausted, there is ground of complaint that some surgeons regard as suitable for operation all cases of chronic digestive disorder, and open the abdomen without troubling to investigate the stomach by the means which have been placed at their disposal by the labours of physicians. In illustration of the abuse of stomach surgery he mentions the case of a man who suffered from gastric crises whose stomach was opened four times by different operators before locomotor ataxy was diagnosed. The attitude assumed by Dr. Delangre on this question of chronic dyspepsia as an indication for operation is plain; he says that "surgical intervention if practised systematically in all obstinate dyspepsias can only have for its result an operative success followed by a therapeutic failure." According to Leriche's statistics the immediate mortality after stomach operations was in 1,239 cases 25 per cent., but particular operators have lowered this considerably, the Mayos, for example, to 9.5 per cent., and a series of 25 cases with only 1 death; the immediate mortality after gastrectomy is 39 per cent. Delangre follows Hartmann and Terrier in relying upon stasis as the chief indication for gastro-enterostomy, and in this he is right. Operation for ulcer of the stomach he considers is not justified until after prolonged and strict medical treatment has proved unsuccessful. He deprecates operating for hæmorrhage, but where there is constant small bleeding exploration is permissible to "see what can be done"; often all that can be done is to perform a gastro-enterostomy, which gives very satisfactory results. Perforation and pyloric stenosis due to cicatrix are recognized as indications for operation, but he omits to refer to duodenal ulcer. Resection of the ulcer is now seldom performed, and should only be done if cancer is suspected, or where it is on the anterior surface or great curvature; but Ricard speaks of it as a "useless and dangerous practice." The usual operation for chronic ulcer is gastro-enterostomy. Hochenegg found that out of 94 cases so treated 83 per cent. were completely cured and 12 per cent. underwent considerable improvement. His pupil Fibisch experimented on animals by making artificial ulcers of the stomach; one-half of the animals were subjected to gastro-enterostomy and the other half were allowed to remain as controls. The result was that the ulcers in the animals operated upon healed, while in the others they continued to increase in size. After the operation the diet should contain a considerable quantity of fat in order to diminish the secretion of hydrochloric acid, and oil should be given by the mouth. Dr. Delangre accepts the statistics of Lebert, which show that 9 per cent. of cancers of the stomach originate from ulcers; and he holds that where the surgeon suspects early cancerous transformation he is justified in resecting the ulcer and performing a gastro-enterostomy. Gastro-enterostomy is the operation for perigastric adhesions, for total symphysis of

the stomach if it is possible, and for all cases of non-cancerous pyloric stenosis with stasis whatever may be the cause. In non-malignant stenosis of the cardia the treatment should be dilatation by bougies through the œsophagus; if this is impossible, the stomach may be opened and the cardia dilated from below. Operations are not advised for simple atonic dilatation, and he speaks of the condition as one in which the knife has been greatly abused. He has no confidence in either gastrotomy or gastroplication. He mentions the exceptional case of severe ptosis with dilatation and intense gastritis treated successfully by Jönnesco by gastropexy, gastrotomy, and gastro-enterostomy. He approves of gastro-enterostomy in hourglass stomach and in tetany caused by dilated stomach. In acute dilatation of the stomach he recommends emptying the stomach by the tube and washing it out. We have not referred to the purely surgical conditions included in the book, as about these there is no difference of opinion. We cordially recommend Dr. Delangre as a safe guide on the matters with which he deals, and should be glad to believe that all surgeons accepted the principles laid down by him.

The monograph on nervous dyspepsia, by Dr. GEORGES L. DREYFUS,² is an attempt to summarize the somewhat discordant accounts that have been published by different authorities during the last thirty years, and to restate the case by showing that there are a good many different conditions which have been included under this heading. He defines nervous dyspepsia as a condition which does not depend upon any disease of the stomach, and is in fact not an independent condition, or to be regarded as a disease in itself any more than jaundice and dropsy. It is a group of symptoms made up of a combination of gastric and nervous ailments, but the latter are to be considered as primary. They may belong to various neuroses or psychoneuroses. It is of course possible that organic disease may develop in association with an undoubted psychosis, it is therefore necessary in all cases to make a careful examination of the stomach, and to exclude organic disease by the use of all the diagnostic means in our power. Such an examination is essential, and can do no harm. The prognosis depends upon the cause. Local stomach treatment is generally out of place. If it does good at all it can only be by suggestion. Strict diet is useless, as it only tends to confirm the belief that the stomach is really at fault, but we may suggest that it is often necessary in the treatment of these cases to begin by giving the simplest food. Pawlow's experiments indicate the close relation that exists between psychical impressions and digestion, and Dr. Dreyfus suggests that this connexion may be even closer than anything we at present imagine. He believes that in all cases of nervous dyspepsia psychical symptoms may be found if they are looked for carefully, and he is disposed to say that where they do not exist the case is not one of nervous dyspepsia, but a true stomach disease. He gives an interesting but somewhat one-sided historical account of the disease, and divides the cases into four groups. The first includes psycho-pathological conditions developing in degenerates with dyspeptic symptoms, and this group he subdivides into four varieties: (1) Where the psychopathy is the cause of the nervo-dyspeptic symptoms; (2) psychical dyspepsia; (3) hysterical dyspepsia; (4) "cyclothymic" dyspepsia. The second group includes acquired neurasthenia with dyspeptic troubles; the third, cases dependent upon changes in the innervation of the stomach; and the fourth cases depending upon alterations of the internal secretions. It is notable that he has very little to say about Groups 3 and 4. As may be inferred from this classification, and from what has been said above, he utterly repudiates the position maintained by some writers, that the nervous symptoms are secondary to and depend upon stomach derangement, and in this we think he is upon solid ground.

HEART DISEASE.

In a series of lectures delivered in 1901 Professor PAWLINOW of Moscow brought prominently forward the somewhat neglected observations of Duroziez on congenital narrowing of the mitral valve and its results upon the whole

¹ *Indications Opératoires dans les Affections de l'Estomac.* Par Dr. A. Delangre. Paris: Vigot Frères. 1903. (Roy. 8vo, pp. 188. Fr. 5.)

² *Ueber Nervöse Dyspepsie.* Von Dr. Georges L. Dreyfus. Mit einleitenden Worten von Professor Dr. L. Krehl. Jena: Gustav Fischer. 1908. (Roy. 8vo, pp. 108. M. 2.50.)

most rapidly rejuvenated whilst we are most rapidly growing old, for our nuclei are rapidly increasing in number so long as we continue to grow rapidly. Surely rejuvenation depends not upon the increase of nuclei, but upon the cause of the increase of nuclei; that cause is not known, and Professor Minot throws no light on it, but we know that the increase, in all bisexual and some unisexual animals, follows the union of two cells, both of which are old of their kind, and one of which, as it consists in many cases of very specially differentiated protoplasm, would, in Professor Minot's sense, be markedly senescent, according to his second law. Moreover, the first phase of rejuvenation, as we see it in the higher forms, is associated with a diminution, not with an increase, of nuclei, for it is initiated by the fusion of two nuclei to form one. The first law is not in accord with facts, and cannot stand. The validity of the second, which states the causes of senescence, depends very much on what is meant by senescence. If we are agreed that a cell is old because it has attained its maximum size and specialization, we may admit the conclusion the so-called law suggests, but in that case the nervous system must be nearly senescent when the child is born, though it is capable of doing seventy or more years of good work. Capability would appear to be a better criterion of age than structure or size, but if the point is waived, the deduction that natural death is the consequence of cellular differentiation is not necessarily admitted. On the contrary, it is obvious that the cells of the muscular and nervous systems may exist for many years after their growth and specialization is completed, and there is no reason to believe that they cease to function because they have achieved their complete size and differentiation. Professor Minot's book will stimulate thought, even if his conclusions do not secure acceptance; but he himself will probably admit that he has neither found the key of the door of life, nor pierced the veil which guards the secrets of death.

NEURASTHENIA.

In a very readable book on the psychology of neurasthenics¹ Dr. PAUL HARTENBERG describes and classifies the various states of consciousness commonly met with in cases of neurasthenia. Before doing so, however, and in order to explain the underlying unity of mechanism producing symptoms so varied as those exhibited by this disorder, the author exposes his own theoretical conceptions of the nature of neurasthenia. This may be put in one sentence: Neurasthenia is, for Dr. Hartenberg, the expression of a diminished activity of nervous matter, variously produced. It is a nervous disorder of which fatigue is the essential stigma and criterion. Dividing the symptoms into physical and psychical, the author considers under the latter heading not only simple psychical asthenia and states of mental and emotional depression and volitional insufficiency, but psychic complications, including phobias, tics, impulses, obsessions, sexual perversions, hypochondria, and melancholia. To all of these mental complications Dr. Hartenberg attaches a certain importance, but he is careful to point out that, notwithstanding their frequent appearance, neurasthenia is not a mental malady—that is, the mental troubles are neither primitive nor essential, but are only the conscious reflection and appreciation of disordered working of the entire nervous system, neurasthenia being thus the expression of a diffuse disorder of neural activity and not a disorder of ideal association or a *maladie par représentation*. Neurasthenia is thus sharply defined from hysteria, which is a *maladie par auto-suggestion*, and also, for the same reason, differs in nature from psychasthenia and melancholia. In these latter states the physical condition is the objectivation of a mental state; in neurasthenia the mental condition is the reflection of a physical state. In applying the general principles of neurasthenia to the appearance of phobias, obsessions, etc., the author assumes in each of these cases a constitutional cerebral defect—that is, that psychasthenia is the “neurasthenia of the degenerate.” Though somewhat of a misnomer—for the book is by no means a thorough psychological study—we can commend Dr. Hartenberg's work as an interesting exposition of the symptomatology of neurasthenia.

Dr. BÉNI-BARDE, who is the author of several works on hydrotherapy in the treatment of diseases of the nervous system, has composed a work of considerable size upon neurasthenia,² which is to form the first of a series of clinical works, the subsequent volumes to deal successively with hysteria, exophthalmic goitre, psychasthenia, etc. After examining the numerous causes of neurasthenia, and after giving a general description of its symptomatology and the three classes—essential, peripheral or reflex, and prodromal or symptomatic—into which he divides this disorder, Dr. Béni-Barde, at great length and with an infinity of detail, discusses the individual bodily disturbances which appear to act as immediate exciting causes; their relation to the neurasthenic condition, and the indications afforded for treatment, with particular reference to hydropathic treatment, of which he is a strenuous and eloquent advocate. In conclusion, after reviewing and criticizing the whole of the various theories—nervous, nutritive, toxic, traumatic, and so on—which have been advanced to explain its pathogenesis, the author gives his own conclusion in the very general statement that “neurasthenia consists of a perturbation of the function devolving upon encephalic zones,” which, at first indefinite in its effects, begins by disturbing the “functional irritability” inherent in the divers tissues and zones, and ends by injuring the “nutritive irritability” on which depends cellular regeneration. Which form the neurasthenia may take depends on the combination and interplay of inherent or constitutional and extrinsic or environmental conditions, these deciding the essential, cerebral, or psychic form (cerebrasthenia or psychasthenia); or the cerebro-spinal form; or the cardio-vascular, or gastro-intestinal forms, etc., as the case may be. In all cases the author praises the advantages of hydrotherapy, in particular when combined with psychotherapeutic measures, but otherwise his book is not very enlightening.

RADIO-ACTIVITY.

THE public interest taken in radium and in the group of phenomena classed together as radio-active serves as a sufficient excuse for the appearance of Mr. C. W. RAFFETY'S introduction to the subject.³ Its chief claim to merit is its striking sanity. The author has been particularly careful to eliminate all matter that is sensational and disputed, and he has carried this principle so far as to exclude from his account of the subject the transmutation of copper into lithium that has been claimed to be an effect of the action of radium. For several other reasons besides its sanity the book will prove popular. It contains a clear, straightforward account of the subject, explaining how the discoveries have been made, what is their bearing on modern theories as to the constitution of matter, and how the phenomena may be observed. In dealing with the spintharoscope, the highly suggestive remark is made that the instrument affords the observer probably the only distinct existing opportunity of watching for himself directly the action of the individual atom. Clear expression is given to the differences existing between the various rays, and readers will be grateful to Mr. Raffety for having added for reference a short appendix summarizing their properties and giving tables of the periods of the radio-active elements. The closing pages of the book are taken up with a description of some of the simpler experiments feasible with inexpensive apparatus. Hints are given to those who wish to lecture on radium as to the precautions they must take to ensure success. The book, in fact, without being brilliant, is a sound and most readable popular treatise on radio-activity. But why will Mr. Raffety interpose adverbs between the constituent parts of his infinitives?

PHYSIOLOGICAL CHEMISTRY.

ALTHOUGH it is only about two years since Professor EMIL ADBERHALDEN published the first edition of his *Lehrbuch*, the second edition⁴ is now to hand. One tribute to the

¹ *La Neurasthénie. Les vrais et les faux neurasthéniques.* By Dr. Béni-Barde. Paris: Masson et Cie. 1908. (Roy. 8vo, pp. 500. Fr. 8.)

² *An Introduction to the Science of Radio-Activity.* By Charles W. Raffety. With illustrations. London: Longmans, Green and Co. 1909. (Post 8vo, pp. 220. 4s. 6d.)

³ *Lehrbuch der physiologischen Chemie, in zwei und dreissig Vorlesungen.* By E. Aderhaldden. Second edition. Berlin and Vienna: Urban und Schwarzenberg. 1902. (Sup. roy. 8vo, pp. 384, 12 illustrations. M. 24.)

⁴ *Psychologie des Neurasthéniques.* By Dr. Paul Hartenberg. Paris: Félix Alcan. 1908. (Cr. 8vo, pp. 288. Fr. 5.00.)

excellence of the book is the fact that it has been translated into English; the early appearance of a second edition is another. We need say no more about it than that the work is thoroughly up to date, and that its author is eminently well qualified to write an authoritative textbook; the matter, moreover, is presented in a clear and readable form.

Another work from the same pen is also before us.¹¹ It deals with recent researches in the chemistry of proteins, in which region of science we owe so much to Professor ABDERHALDEN himself. It does not treat of all the problems concerning proteins, but merely of their pure chemistry. The booklet is a reprint of the chapter Professor Abderhalden contributed to the more ambitious textbook which is appearing in fasciculi under the editorship of Dr. Carl Oppenheimer, and which has been already noticed in these columns. In that publication other aspects of proteins (biological, etc.) are contributed by other authors. Many readers, however, will find it convenient to have Professor Abderhalden's excellent article in separate form.

But it is not only Germany which is prolific in publications of this kind just now. Three more of the monographs on biochemistry which Messrs. Longmans are publishing have just made their appearance. Two of these are written by Dr. R. H. ADERS PLIMMER, and both deal with the *Chemical Constitution of the Proteins*.¹² Part I with their cleavage products and Part II with the attempts made to synthesize them from their cleavage products. The work traverses much the same ground as in Abderhalden's smaller book just noticed, and those that buy the one will not require the other. Dr. Plimmer has also the gift of clear exposition, and the work is fully abreast of recent advances in science. It is particularly well suited for English-speaking students and researchers, and we note with satisfaction that the terminology adopted is that recommended by the Protein Nomenclature Committee of our physiological and chemical societies acting in conjunction with a similar committee in America.

The third monograph deals with *The General Characters of the Proteins*, and is written by Dr. S. B. SCHRYVER.¹³ The characters included are physical (solubilities, crystallization, optical activity, heat coagulation, and the like), chemical (tests, protein compounds, oxidation products, distribution of nitrogen, etc.), and biological (precipitin reactions). The whole forms a useful and lucid contribution to protein literature.

The French contribution before us deals with the synthesis and constitution of proteins,¹⁴ but is not more than a pamphlet. It gives in outline an account of protein constitution, dealing mainly, of course, with the more recent acquisitions to knowledge on this subject, the importance and interest of which is manifested by so many publications in different languages relating to it.

Furthermore the twelfth and thirteenth fasciculi of OPPENHEIMER'S *Handbuch*¹⁵ are just to hand. Dr. Franz Müller deals in several articles with animal pigments (of blood, bile, urine, etc.); Professor von Fürth with melanins and similar pigments; F. Samuel with various products of protein cleavage; and Wolfgang Ostwald with the general characters of colloids.

THE CAUSATION OF SEX.

In a monograph entitled *The Causation of Sex*,¹⁶ Mr. E. RUMLEY DAWSON claims to have solved the problem of sex

causation and to have formulated a new theory. The theory consists of two parts; the first is that sex is not due to the male but to the female parent, and the second that the right ovary produces male and the left female ova. So far as the first part of his theory is concerned the author may claim priority, for he put it forward in 1900, but in urging this point he does not stand so entirely alone as he seems to imagine, for in a paper entitled, *The Determination of Sex in Animal Development*, which appeared in 1902, Dr. J. Beard makes the following statement: "The determination of sex for the next generation thus lies with germ cells of the female metazoan organism," but the data on which he bases the opinion are quite different from those upon which Mr. Rumley Dawson depends. The second part of the theory had practically been stated, before Mr. Rumley Dawson's first communication on the subject, by Dr. Tuckey. Mr. Dawson insists that Dr. Tuckey did not dissociate the male parent from any part in sex causation, but when he came to the conclusion that boys were derived from the right and girls from the left ovary he could scarcely have ascribed much potency in sex production to the father. A further point upon which Mr. Dawson insists is the alternate action of the two ovaries, and as regards this he is in conformity with the opinion of Negrier, and the idea has also obtained support from the observations of other inquirers. If the contentions that the ovaries produce ova of opposite sexes and that the ovaries act alternately are well founded then it might be possible to foretell the sex of a coming child, the sex of the previous child, the date of its birth, and the reappearance of menstruation in the mother being known. The plan Mr. Dawson adopts is to go forty weeks back from the last child's birthday to find the month in which the ovum was fertilized which yielded the child. The sex of that child being known, proceed alternately from the month in which the ovum from which it grew was fertilized to the tenth ovulation period prior to the expected month of the birth of the coming child, allowing an extra or thirteenth ovulation between December and the January of the following year, because there are thirteen ovulations per annum. Using this rule, Mr. Dawson claims to have had 97 per cent. of successes, and the 3 per cent. of failures he attributes to the inability of the mothers to forecast correctly the month of confinement. If other observers, using the data, are equally successful, there will be much to be said for his theory, but it is certainly not proved by the anatomical, physiological, and pathological data Mr. Dawson uses to support it, nor is his case strengthened by the one-sided way in which he uses the evidence at his disposal.

NOTES ON BOOKS.

DR. PRICE-BROWN is a physician of Toronto who finds relaxation from the strenuous life of a practitioner of medicine, who has to battle with facts, in wooing the Muse of Fiction. In *The Fan*¹⁷ is a pretty story of a wife's devotion. The scene is laid in Canada during the war of 1812 between England and the United States, and the plot is merely the story of the foundation of an English military settlement on the shores of Lake Huron. Helen Manning, the wife of a young Peninsular officer, insists upon accompanying her husband when his regiment is ordered to America, and though she is the only lady in camp she follows the men in the long march from Halifax to Georgian Bay on Lake Huron, and braves all dangers and discomforts to remain by her husband's side whilst the fort is being built. The tale is told partly in the form of Helen's diary, and is principally an account of her adventures whilst in camp and on the march, when she cheers the men and wins all hearts by her sweetness and courage. A second story, the love story of a girl hesitating between her two lovers, a Canadian and an Englishman, is introduced, but the plot is very slight. Dr. Price-Brown seems more at home when he is writing of his native forests and lakes and describing the terrors of a Canadian winter than he is when telling a story. The chief interest of the book lies in the descriptions of Canadian life and scenery, which are excellent. The character drawing, on the contrary, is not so good, and the language is a trifle too modern, not to say slangy, for the early days of the last century; ladies of that time did not speak of something being "just lovely." or

"awfully jolly." But there is a charming sketch of a French Canadian, Bateese, whose broken talk and quaint old songs, half-English, half-French, are delightful. It is a pleasant story pleasantly told, and it points a useful moral. It brings home to the present-day English people what our colonies have cost us in the past, and what English men and women have suffered in helping to found and to retain them.

In his little book on the *Cure of Rupture by Paraffin Injections*,¹⁸ Dr. MILLER describes the method of injecting paraffin into the loose tissue surrounding the sac. The author fails to convince us that this method is destined, as he thinks, to play an important part in the surgical treatment of reducible hernia. Most readers will be disposed to regard it as crude and uncertain, and an impression that it is by no means simple nor, indeed, quite free from danger, is suggested by the statement that "only the operator who is thoroughly acquainted with the manner of disposition of paraffin should attempt the injection of hernia." The clinical report at the end of the book is far too scanty and incomplete to warrant any definite conclusions on the results of this treatment.

The pains taken by Dr. BRICKNER and his colleagues to extend and to improve still further their *Surgical Suggestions*,¹⁹ will, there can be no doubt, secure for their work a continuance of the favour it has hitherto received from American surgeons. This handy volume is truly, as is claimed, "packed full" of information, and this, though to English readers it may seem here and there to be strange and somewhat erratic, will, on the whole, be found very useful and in accordance with the latest principles of surgical practice. It is essentially a work for experienced surgeons, and not a mere collection of hints on elementary matters.

We have received the new edition of Mrs. Beeton's *Cookery Book*²⁰ printed from new type, and revised throughout. English cookery has always been strong in plain sweets and weak in vegetables, and the editors of the new edition have endeavoured to improve the recipes for the cooking of vegetables without prejudice to the recipes for puddings. The book, which is still moderate in price (1s.), has been enlarged, and contains a number of coloured illustrations.

MEDICAL AND SURGICAL APPLIANCES.

Saline Infusion Indicator.

MR. R. DOUGLAS LAURIE, M.B., Ch.B. Edin., House-Physician, Royal Hants County Hospital, Winchester, writes: In the administration of saline continuously either per rectum or beneath the skin, the great difficulty lies in knowing whether at any given moment the fluid is flowing, and if so, at what rate. To overcome this I have made the indicator, which is put in circuit with the rubber tube leading from the saline reservoir to the patient. The tube is so constructed that it encloses a volume of air which can neither escape upwards to the reservoir, nor downwards to the patient, but does not hinder the flow of the fluid. It consists of a narrow glass tube sealed into the upper end of a larger tube, and projecting towards the centre of the latter. As the saline flows, drops are formed on the end of the inner tube, and the fall of these indicates the rate of flow. The inner tube is of such a size that each drop is approximately one minim, and by thus counting the drops per minute the rate of flow can readily be estimated. (The number of drops per minute divided by 8 gives the rate in ounces per hour.) The indicator should be connected with the rubber tubing shortly after it leaves the reservoir, and in such a position that it can hang vertically. A clamp (preferably a screw clamp) is placed

on the rubber tubing just above the indicator, and the flow regulated by this. The indicator is of glass, and can readily be sterilized in carbolic. Messrs. Allen and Hanburys, Limited, supply the indicator at 12s. per dozen.

An Auto-Gloving Machine.

In connexion with the exhibition of new appliances at Sheffield last year brief allusion was made to an auto-gloving device on view. Since then the makers, Messrs. Hoefftcke, of 21, Woodstock Street, W., have made a material alteration in its manufacture, with the result that it is now in every respect an admirable piece of theatre furniture. As will be gathered from the accompanying woodcut, it consists of a vertical cylinder, with an opening just large enough to admit of ready insertion of the hand and wrist. The sterilized glove is hung in the opening with its wrist-piece turned over the edge of it. The operator presses a foot lever, which action results in the instant formation of a vacuum in the cylinder. The

glove responds, and, thanks to its elasticity, dilates evenly in all its parts, so that the hand slips in without difficulty. The hand in place, the lever is released; the vacuum disappears, and in a flash the hand is neatly gloved. The whole operation, whether the hands are wet or dry, hardly takes five seconds. Though the whole apparatus takes to pieces and can be sterilized, the makers have thought it well to protect the gloves from all possible contact with the interior of the machine by providing a bag which hangs down inside the cylinder from a false collar at its upper opening. This, of course, can be taken out, sterilized, and replaced as often as desired. The apparatus shown in the engraving is to glove both hands simultaneously, but single gloving machines are also supplied.

RURAL AND COUNTY NURSING ASSOCIATIONS.

We have published recently several letters under the general heading of "Rural Nursing Associations" in which the writers have given instances of defects in the organization and administration of rural nursing associations. The matter is at present under the consideration of the Medico-Political Committee, which we understand will report at an early date; meanwhile it appears to be advisable to print for the information of members the new rules which the Queen Victoria's Jubilee Institute for Nurses suggests for the guidance of local rural nursing associations. We may add that Rule 9 has been formulated largely in consequence of representations which

have been made to the Queen Victoria's Jubilee Institute Nurses on behalf of the medical profession.

QUEEN VICTORIA'S JUBILEE INSTITUTE FOR NURSES.

SUGGESTED RULES AND INFORMATION FOR LOCAL ASSOCIATIONS EMPLOYING VILLAGE NURSES.

1. The Association includes the parishes of and is in affiliation with the County Nursing Association.

2. The nurse will work under the Committee of the Association, and will be under the supervision of the County Superintendent. If a midwife she will be also under the inspection of the local supervising authority as laid down by the Central Midwives Board.

3. The services of the nurse may be secured by payment of an annual subscription on the following scale:

Labourers (wages not exceeding 20s. per week), 2s. per annum. Artizans and small tradespeople, 3s. 6d. to 4s. per annum.

Tradespeople and farmers, 5s. to 10s. per annum.

or, Working people may secure the services of the nurse on payment of 2d. per month for single people, and 4d. per month for a family including aged relatives living with and dependent on the family.

Tradespeople and farmers may employ the nurse for a subscription of 5s. to 10s. per annum, except for midwifery.

4. Subscribers of less than 5s. per annum may engage the nurse as midwife at a fee of not less than 5s. (arrangements as to the nurse taking midwifery work are subject to the wishes of the Committee of each Association.)

Monthly nursing is (free) or (subject to an extra charge of 2s. to working people earning under 20s. a week).

A charge for monthly nursing of (3s. 6d. to 5s.) is made to those subscribing 5s. and under to the Association. Notice of (2) or (3) months must in any case be given to the (nurse) or (Honorary Secretary) and the charge prepaid.

Other charges by arrangement.

5. Night duty is not expected of the nurse, except in critical cases, when a small charge (4d. to 1s. 6d.) may be made, or in maternity cases, which are free.

6. The nurse's services, if not required for subscribers, may be supplied to non-subscribers, but only at higher rates (to be fixed by the Committee).

7. The nurse will attend cases daily when necessary.

8. The nurse will not attend infectious cases. The County Association will, when possible, arrange to supply a nurse on terms to be arranged between the County and local Association for any case of emergency or special difficulty, and also for holiday work.

9. In all cases of general sick nursing the attendance of the nurse must be sanctioned by the medical man, it being understood that her attendance on such cases does not interfere with her engagements to lying-in women. When she has anything to communicate to the doctor she shall do so in writing, and it is hoped the doctor will do the same to avoid leaving verbal messages with patients or their friends.

The nurse may attend a patient on application or in emergency, but must not continue to visit without a medical man being informed. Should the nurse advise the patient to have a doctor and the patient refuse, the nurse may no longer attend this patient except in case of urgency. She must in any case report the matter to her Secretary.

10. The nurse when on duty will wear the uniform dress and no ornaments. No presents or beer, wine, or spirits of any kind may be accepted by her.

11. The nurse is strictly forbidden to interfere in any way with the religious opinions of her patients or their friends, and she shall consider as strictly confidential all matters which shall come to her knowledge concerning her patients. She is not allowed (except in cases of immediate necessity, which should be reported at once to the Honorary Secretary) to provide nourishment or relief.

12. It is the nurse's duty to do all that concerns the person and bed of the patients, and she is responsible for their personal cleanliness. She must see the room is ventilated and cleaned, and do her best to improve the general surroundings. When the relations of the patient can be taught how to keep the room in nursing order they should be encouraged to do so.

13. The nurse shall not, as a rule, be required to be on duty more than eight hours daily, and on Sundays she will only attend urgent cases. She is entitled to (one month's) or (three weeks') holiday yearly, the date to be fixed by the Committee.

14. The nurse will keep a register of her patients for the Committee and send a report of her own work as required to the County Superintendent on the forms provided. It is suggested that one of the Honorary Secretaries with one of the ladies of the Committee should see the nurse and inspect her books one afternoon each week.

15. The nurse shall be responsible to the Committee for all appliances and garments lent to patients being returned in good order.

16. The nurse must be punctual in going to her work, keeping a register of her times in the book provided for the purpose. She must leave word at her rooms (on a slate provided for the purpose) where she is likely to be found in case of emergency, and the approximate hour of her return.

17. Applications for the services of the nurse may be made to her. Applications for the nurse's services should be made as early as possible in the day.

PISTOIA GOUT POWDERS.

THERE was a powder for gout known to an earlier generation under the name of the "Portland Gout Powder." This, according to the prescription given by Jourdan in the *Pharmacie Universelle* (1826), consisted of Gentian root, round birthwort root (*Aristolochia rotunda*), ground pine root (*Teucrium chamaepitys*), the tops of germander (*Teucrium chamaedrys*), and of the lesser centaury (*Eriotheca centaurium*), of each equal parts to be ground separately to a fine powder and mixed; dose, half a teaspoonful. Jourdan gives of this three variants, in one of which the gentian is replaced by guaiacum.

For some years past a good deal has been heard about the Pistoia gout powders. A pamphlet entitled *The anti-gouty powders of the R.R. Benedictine Mothers of Pistoia for the treatment of a gouty source* (Rome, 1904) presents a curious resemblance to the advertising pamphlets issued by ordinary nostrum dealers. There is a short disquisition on gout written in very old English; this is followed by a translation of a large number of testimonials to the virtues of the powder, and this again by the following "Warning to our Customers":

Having known that in some towns of Italy, and even in Pistoia, some anti-gouty drug circulates under the name of "Vegetal Anti-gouty Powders of the Cloister" or under other names alike, making every body trust that they come from our Monastery, we think ourselves, in duty bound, to remember to our Customers that no deposit of our Anti-gouty Powders is to be found neither in Pistoia nor in other towns or places in Italy or abroad, and that we have accorded to nobody the faculty of preparing or selling them.

Consequently every anti-gouty remedy which in any way should be made known as coming from this Monastery, must be considered as a product of vulgar falsification and adulteration.

The label on some boxes of the powder states that it is based on gentian and Indian wood which is one of the synonyms of guaiacum.

The pamphlet, which has already been quoted, states that the powders do not contain colchicum, belladonna, or any other poisonous substance, but

are a composition of medicinal grasses, none of which can ever have a pernicious effect upon the health, whatever may be the state of the person who uses it.

It is asserted that "often many miraculous cures are obtained," but it appears that the treatment must be a prolonged one, for the pamphlet further states that:

When it is question of a first affection or of a light gouty attack, the treatment of a whole year without interruption can in general be sufficient; because it is necessary for the blood to stay under the action essentially depurative of the drug during four seasons.

But when the illness is old, a year of treatment cannot of course be enough to extirpate entirely the distempore, and the use of the drug must be protracted till necessary.

MM. Guignard, Collin, Chastaing, and Barillot give the following formula for the Pistoia gout powder:

I.			
Colechicum corn	10 parts
Bryony root	10 "
Betony (root, stem, and leaves)	50 "
Gentian root...	10 "
Camomile (chiefly stem, leaves, a little root, and flowers)	10 "

M. Collin is one of the leading authorities on the microscopic characters of powdered vegetable drugs, and on examination of a specimen of the powder which recently came into our hands it showed characters consistent with this formula; such small differences as were observed were only such as might be expected between specimens grown under different conditions of soil, climate, etc.

Another formula which has been published for the powders is as follows, but the sample we examined agreed more nearly with No. 1:

II.			
Colechicum corn	20 parts
Bryony root	10 "
Betony root	40 "
Gentian root...	10 "
Camomile	10 "

"THE CHILDREN'S CHARTER."

The Children Act, 1908, which came into force on Thursday last, has been well called "the children's charter." The Act extends, and to some extent codifies, previous Acts dealing with children, and repeals many clauses in other Acts. The new Act is divided into six parts:—

1. Infant life protection.
2. The prevention of cruelty to children and young persons.
3. Juvenile smoking.
4. Reformatory and industrial schools.
5. Juvenile offenders.
6. Miscellaneous and general.

INFANT LIFE PROTECTION.

Under the Infant Life Protection Act, 1897, only foster parents who received more than one infant under the age of 5 years were brought under inspection. The new Act applies to an infant in single care and extends the age to 7 years. Its first clause is as follows:

1. Where a person undertakes for reward the nursing or maintenance of one or more infants under the age of 7 years apart from their parents or having no parents, he shall, within forty-eight hours from the reception of any such infant, give notice in writing thereof to the local authority.

The foster parent who changes his or her residence must give notice to the local authority within forty-eight hours, and within the same period must give notice of the death or removal of any infant previously under his or her care, and within twenty-four hours must give notice of death to the coroner. Any person failing to give due notice in any case will be guilty of an offence, and if the maintenance of the infant has been paid for in whole or in part by a lump sum, it or any part of it will be liable to forfeiture. Statutory obligation is laid upon every local authority to provide for the execution of this part of the Act, and if on inquiry it appears that there are any persons who undertake the nursing and maintenance of such infants the local authority must appoint infant protection visitors, who shall satisfy themselves as to the proper nursing and maintenance of the infants and give necessary advice or directions. The visitor will have authority to apply either to a justice or to the local authority for an order directing him to remove an infant to a place of safety if it appears that the infant is being nursed in overcrowded, dangerous, or insanitary premises, or by a person who by reason of negligence, ignorance, inebriety, immorality, criminal conduct, or other similar cause, is unfit to have care of it. Foster parents are forbidden to insure the life of a nurse-child, and an insurance company which issues a policy on the life of such an infant will be guilty of an offence. Persons guilty of an offence under this part of the Act will be liable on summary conviction to imprisonment for a term not exceeding six months, or to a fine not exceeding £25. The local authority may exempt from inspection institutions maintained by a philanthropic society or any particular premises within their district which appear to them to be so conducted that it is unnecessary that they should be visited.

PREVENTION OF CRUELTY TO CHILDREN AND YOUNG PERSONS.

The first section of the second part of the Act applies to any person over the age of 16 years who has the custody, charge, or care of any child or young person. If such a person assaults, ill-treats, neglects, abandons, or exposes a child or young person, or allows a child or young person to be treated in a manner likely to cause unnecessary suffering or injury to health, including mental health, such person shall be guilty of a misdemeanour, and shall be liable (a), if convicted on indictment, to a fine not exceeding £100, or to imprisonment, with or without hard labour, for any term not exceeding two years, or to both penalties; or (b), on summary conviction, to a fine not exceeding £25, or imprisonment for a term not exceeding six months, either or both. It is further provided that a parent or other person legally liable for the maintenance of a child or young person shall be deemed to have neglected him in a manner likely to cause injury to his health if he has failed to provide adequate food, clothing, medical aid, or lodging, or, if unable to make such pro-

vision, if he fail to take steps to procure the same under the Poor Law. A person may be convicted of an offence under the section notwithstanding that the actual suffering or injury to health has been obviated by the action of another person, or notwithstanding that the child has died. If it be proved that a person convicted under this section was directly or indirectly interested in the insurance of the child or young person, the penalties are increased to a fine of £200, or penal servitude for five years on conviction on indictment; in the case of summary conviction, the court, in determining the sentence, shall take into consideration the fact that the person was interested in the insurance.

SUFFOCATION OF INFANTS.

The following is the clause with reference to overlying:

Where it is proved that the death of an infant under 3 years of age was caused by suffocation (not being suffocation caused by disease or the presence of any foreign body in the throat or air passages of the infant) whilst the infant was in bed with some other person over 16 years of age, and that that other person was at the time of going to bed under the influence of drink, that other person shall be deemed to have neglected the infant in a manner likely to cause injury to its health within the meaning of this part of this Act.

BURNING.

If a person in charge of a child under the age of 7 years allows it to be in any room containing an open fire not sufficiently protected to guard against the risk of burning or scalding without taking reasonable precautions, and the child is killed or suffers injury, he or she is made liable on summary conviction to a fine not exceeding £10.

BROTHELS; PROSTITUTION.

A person having the custody, charge, or care of a child or young person between the ages of 4 and 16 years who allows it to reside in or frequent a brothel is liable to a fine of £25, or imprisonment for not more than six months, or to both penalties. Any such custodian who causes or encourages the seduction or prostitution of a girl under 16 is liable to imprisonment for any term not exceeding two years, and he shall be deemed to have encouraged such seduction or prostitution if he has allowed her to consort with or enter or continue in the employment of a prostitute or a person of known immoral character.

A constable may take into custody without warrant any person who within his view commits an offence under this part of the Act, or who the constable has reason to believe has committed such an offence, and the constable or any person authorized by a justice may take to a place of safety any child or young person in respect to whom such an offence has been, or there is reason to believe has been, committed.

HABITUAL DRUNKARDS.

If it appears to the court before which any person is convicted of an offence of cruelty under the Act, that he or she, being the parent of the child or living with the parent of the child, is an habitual drunkard, the court, in lieu of sentencing the person to imprisonment, has power to order his or her detention in a retreat under the Inebriates Acts, provided that the person consents.

A board of guardians, and in London a local authority, is given power to institute proceedings under this part of the Act.

JUVENILE SMOKING.

The sale of cigarettes or cigarette papers to a person under the age of 16 years is rendered illegal, and the seller is subject to a penalty not exceeding £2 for the first offence, £5 for the second, and £10 for a third or subsequent offence. A court of summary jurisdiction may direct the removal of an automatic machine supplying cigarettes. A person will not be guilty of an offence for selling tobacco other than cigarettes to a person under the age of 16 years if he did not know and had no reason to believe that it was for the use of that person; but the Act will apply to smoking mixtures intended as a substitute for tobacco in like manner as to cigarettes.

REFORMATORY AND INDUSTRIAL SCHOOLS.

The object of this part of the Act is to enable courts to deal with youthful offenders without sending them to prison. A youthful offender between 12 and 16 years of age may be committed by the court to a certified reformatory school. The court will also have power to

send to a certified industrial school any child apparently under the age of 14 years who is found begging, wandering without home or place of abode or destitute, under the care of a parent or guardian of criminal or drunken habits, or who frequents the company of any reputed thief. A parent unable to control a child may take advantage of this section to obtain his committal to an industrial school.

JUVENILE OFFENDERS.

A court of summary jurisdiction, when hearing charges against children or young persons, must in future sit either in a special building or room, or on a different day to that on which ordinary sittings are held. A court is given very large discretion in dealing with a charge and inflicting punishment in the case of a child or young person. In future no child or young person—that is to say, no person under 16—can be sentenced to death. No child—that is to say, no person under 14—shall be sentenced to imprisonment or penal servitude, and no young person—that is to say, no person under the age of 16—shall be sentenced to penal servitude.

ALCOHOL.

Section 119 runs as follows:

If any person gives, or causes to be given, to any child under the age of 5 any intoxicating liquors, except upon the order of a duly qualified medical practitioner, or in case of sickness, or apprehended sickness, or other urgent cause, he shall, on summary conviction, be liable to a fine not exceeding three pounds.

Section 120 excludes children from the bars of licensed premises, and imposes a penalty of forty shillings for the first offence, and £5 for any subsequent offence, not only on the licensee, but also on any person who causes or procures, or appears to cause or procure, a child to go to or to be in the bar of licensed premises during such hours as the bar is open.

VERMINOUS CHILDREN.

Section 122 empowers a local education authority to direct its medical officer or any person deputed by him, to examine the person and clothing of a child in a public elementary school, and if such child is found infected with vermin, or in a foul or filthy condition, the parent or guardian may be ordered to cleanse the person and clothing of the child within twenty-four hours; if the parent or guardian fail to obey the order, the medical officer or his deputy may remove the child, and cause its person and clothing to be properly cleansed.

DETERMINATION OF AGE.

While a court is required to take such evidence as may be forthcoming with regard to the age of a child, it is given power to presume the age.

APPLICATION TO SCOTLAND AND IRELAND.

Sections 132 and 133 are concerned with the modifications necessary to apply the Act to Scotland and Ireland.

THE COMPENSATION ACT AND MEDICAL REFEREES.

DURING the course of an interesting discussion of the Workmen's Compensation Act, which recently occupied the members of the Medico-Legal Society, certain interesting points were brought out as to the present law relating to medical referees. Dr. R. J. COLLIE observed that as the Act now stands a county court judge may only refer a matter to a medical referee on application to the court "by both parties." He suggested that the words "either party" should be substituted. In his view this change would be followed by "a huge slump in bogus cases, in hard swearing, in prolonged litigation, and in the degradation of the working classes." According to Dr. Collie, it is the man who has a bad case who refuses to allow it to be referred to a medical referee. He cited many instances in which, by the astuteness of the medical examiner, the fraud and the malingerer had been detected. One of these was particularly amusing. A man complained of an injury to his back caused by an accident. Accompanied by his wife, he visited a medical man retained by his

employer, and told him that he had no feeling over a particular area of his back. The examiner applied a slight charge of electricity to the area in question. The patient said he did not feel it. The charge was gradually increased until the malingerer, unable to bear the pain any more, uttered a loud cry, and curled up on the floor. His wife rushed into the room to see what was the matter, when the doctor said, "See! I have cured your husband by electricity." This the patient did not deny. He went back to work at once.

Dr. MORLEY, too, instanced one striking case to show how easily fraud on the part of a workman may be detected by a medical man. A dock labourer alleged that, owing to a blow on the head, he had become totally blind. The employer's medical man was given permission to see him in the robing room of a county court, whither the applicant was "led" by his wife. For the purposes of examination, the doctor asked the patient to remove his collar and tie. While the man's attention was distracted, the doctor knocked his stud on the floor. He then, with the ostensible object of testing the man's eyesight, dropped a match on the carpet, and asked the patient to pick it up. The patient professed to be unable to do so, but subsequently, when his attention was off the matter, he picked up his stud with the greatest ease! Needless to say, his application for compensation was dismissed.

With regard to the appointment of medical referees and assessors, it seems to be thought, both by lawyers and doctors, that the law requires amendment. At present a judge may, if he thinks fit, appoint a medical assessor to sit with him. Dr. COLLIE would so alter the Act as to provide that the judge shall, on demand of either party, summon a medical assessor to sit with him. At present some county court judges seldom or never make use of the power which is vested in them. One member of the medical profession said that he had been a medical assessor for nearly ten years, and had never yet been called on to act.

Three county court judges who took part in the discussion made various suggestions on the subject.

His Honour Judge SMYLY said:

It would be a great assistance in every case if a medical referee were present. . . . I have suggested that medical questions should go to the medical referees before they come to the judge at all.

Judge BRAY said:

There are cases in which I am not sure that the medical assessor would be of much assistance, and where it would be a farce to disregard the medical evidence and accept absolutely the opinion of the medical assessor. There is, however, a great deal of untruthful medical evidence given which the judge is really not in a position to appreciate at its true value.

Judge HOWLAND ROBERTS said:

I have derived the greatest assistance from having a medical assessor sitting with me, but it does not do for the judge to lean entirely on the medical assessor, because he ought to be guided to some extent by the medical evidence.

It would seem from these expressions of opinion that the county court judges themselves take the view that assessors should be more frequently appointed. How is the judge to know that there are medical issues until the case is actually before him? If he then decides that the question is one which an assessor should help him to solve, there must be an adjournment at the expense of the parties. It is difficult to understand the attitude taken up by a judge who refuses to call in an assessor when occasion demands. An assessor can detect the medical witness who is "prepared to stretch a point" when the judge cannot.

It is hoped that should the Medico-Legal Society make representations to those in authority with regard to the amendment of the Compensation Act, it will call particular attention to the position of the medical referee.

THE Congress of French-Speaking Alienists and Neurologists will hold its nineteenth meeting this year at Nantes under the presidency of Dr. Vallon. Among the subjects proposed for discussion are chronic forms of chorea, to be introduced by Dr. Sainton, of Paris; and lunatics in the army from the medico-legal point of view, to be introduced by Drs. Graujoux of Paris and Rayneau of Orleans.

REPORT

OF THE

Royal Commission on the
Poor Laws and Relief
of Distress.

REPORT BY DR. J. C. McVAIL.

Dr. J. C. McVAIL, county medical officer for Stirlingshire and Dumbartonshire, undertook at the request of the Royal Commission to inquire into and report on the methods and results of the present system of administering indoor and outdoor Poor Law medical relief in certain unions to be selected from a list drawn up by the Commission.

The inquiry, which began at the end of April, 1907, and terminated at the end of that year, was confined to England and Wales, and with regard to certain inspections Dr. McVail had the assistance of Dr. Joseph William Gill. The rural unions visited were chosen from different parts of the country, and in eleven instances both indoor and outdoor medical relief were studied; in four other rural unions only the workhouses were visited. The urban unions in which both indoor and outdoor inquiries were conducted were King's Norton, in the Birmingham district; Pontypridd in South Wales; Salford; and Hull. Barry Docks, St. Helens, Camberwell, and Edmonton were also visited; and the Whitechapel Infirmary, the Chelsea and Kensington Guardians' Children's Cottage Homes, and the West London Children's (Barrack) Schools were inspected. Dr. McVail deputed Dr. J. R. Currie to visit nine Poor Law dispensaries in the metropolis, two in King's Norton, and four in Salford. The visits to the unions were paid without previous intimation to the guardians or their officers.

Questions of medical relief and other relief are so closely related that Dr. McVail in reporting on medical relief found it impossible to keep clear of references to some other questions. The recommendations and suggestions he makes are of a twofold character, being based, first, on the assumption that the present local organizations will remain but be improved in detail; and, secondly, that there may be a fundamental change in the local authorities, or a transference to county or municipal administration of medical work at present done under the Poor Law, with the object of developing the preventive as distinguished from the curative or palliative side of medical treatment.

Dr. McVail concludes his report by two memoranda. The first one adumbrates a scheme of medical provision institutions maintained partly by members' contributions and partly by public funds, and indicates the possible relation of such a system to the Poor Law, to the great friendly societies, to the present system of free hospital dispensaries (out-patient departments), and to the work of the medical profession. The second memorandum deals with home medical inspection.

The appendices to the report contain notes on the various unions visited, and Dr. Currie's report on the Poor Law dispensaries visited by him.

INADEQUACY OF THE POOR LAW MEDICAL SYSTEM.

We may turn at once to Dr. McVail's general conclusion and quote it in full, drawing particular attention to the truth of the picturesque phrase with which it opens:

Poor Law medical relief, both urban and rural, is a cripple supported on two crutches—the general hospitals on one side, and gratuitous medical work on the other. The general hospitals supplement the workhouse infirmaries, whilst the unpaid work of the district medical officers and other medical men supplements outdoor medical relief. The fact is that the whole system would break down if it were not thus assisted. But it is obvious that such charitable contributions in supplement of the Poor Law cannot be uniform throughout the country. Medical men are not all alike in their willingness to work for nothing, private charity does not equally abound everywhere, general hospitals are not equally well supported everywhere, and are not within convenient distance of every part of the country. At present there is nothing at the same time systematic and complete in the provision made. The systematic part is the Poor Law, whose operations, though national, are

incomplete and insufficient. The completing part is local, and consists in the gratuitous work of the doctors and the assistance of private charity and the general hospitals; but these are not systematic. And I have already given facts to show that medical relief is inadequate in its dealings in respect of paupers, with the most important medical problems of the time, the healthy up-bringing of children, the control of phthisis, and the early preventive treatment of disease.

Dr. McVail condemns a public policy under which an authority representing the community confers personal benefits without any accompanying requirements as to good order or obedience, and maintains that it is not worth while to enter on any reform of the Poor Law unless this policy is changed. In expressing this opinion he specifies the following familiar conditions as among those which he has in mind:

Lazy, drunken loafers are taken into the workhouse to be cleansed and fed, and tended during their recovery from a debauch, or are sheltered and boarded through the inclement weather of winter, and let out again to revert without restriction to their life of misconduct in summer. Prostitutes come in to be treated for the foulest diseases, and go out again to resume their old career. Persons suffering from the most serious and transmissible maladies are afforded relief without prevention of opportunities to inoculate the healthy or contaminate the next generation. Weak-minded girls or dissolute women enter the workhouse to be delivered of illegitimate children, and go away again to return time after time in the same condition. Phthisis cases are maintained in crowded, unventilated houses where there is unrestrained facility to convey the disease to their own offspring. Diabetes cases live on the rates and eat what they please. Infirm men and women unsupported by the Poor Law are allowed to dwell in conditions of the utmost personal and domestic uncleanness. Widows get money for the upkeep of their family without any advice or requirement as to the spending of it or as to the healthy rearing of their children. Outdoor medical attendance is freely and unconditionally provided by the guardians for the drunken and the immoral.

Dr. McVail then makes two sets of recommendations, one to apply if boards of guardians are continued, and the other if they are to be replaced by a comprehensive system for the prevention of disease and the relief of sickness and destitution.

REFORM.

If the guardians are to remain, Dr. McVail advises that the Local Government Board should possess and exercise much greater authority, and should have the power and will to enforce the observance of the rules and regulations which it issues from time to time. He considers:

1. That the administrative areas of most boards of guardians should be greatly enlarged, so that each would have under its control multiple institutions capable of being devoted to separate charities.

2. That both indoor and outdoor medical relief should be under regular and systematic inspection by medical inspectors of the Local Government Board, who should in their reports include a reference to the kind and quality of the work done by medical officers and nurses, indoor and outdoor; to the size and convenience of the areas in which the work is done; to the salaries paid and the sufficiency of the medical and nursing staff provided by the guardians.

3. That the salaries of medical officers should not cover the supply of medicines, and that the minimum fees paid to medical officers, indoor and outdoor, for attending midwifery cases should be increased, and no extra payment made in respect of difficult cases.

4. That the management of phthisis should receive much more attention than at present, and that the sanitary supervision of paupers' houses in which cases are being treated should be regular and thorough, and that to this end the district medical officers should intimate to the medical officer of health all phthisis cases coming officially under their notice, as is now being done in England under the recent order of the Local Government Board; that the boarding-out of suitable cases in country cottages should be arranged for, and that reasonable and properly designed provision should be made in Poor Law sick wards and infirmaries for cases of phthisis which cannot be otherwise dealt with.

5. That epileptics should be treated in separate institutions or colonies, and imbeciles partly by boarding out and partly in special institutions.

6. That readily curable forms of mental derangement, including delirium tremens, should not be certified as

insane until opportunity has been given for recovery in special wards in Poor Law infirmaries or workhouses.

7. That rural boards of guardians should be obliged to contribute to accessible general and special hospitals and convalescent homes, and to use them for suitable cases; but that if general hospitals are not within reach or are not open to paupers, rural boards should, either separately or in combination, provide infirmaries of their own or contribute towards the erection of general hospitals.

8. That in urban areas, so far as cases are received in general hospitals or relieved at public dispensaries, urban boards of guardians should make contributions to the authorities, that urban Poor Law dispensaries should be improved and systematically inspected by the Local Government Board, and that as little restriction as possible should be put on the use of maternity wards by married women not ordinarily receiving Poor Law relief.

9. That all observed unhealthy conditions in houses occupied by paupers should be reported by the district medical officer to the medical officer of health, and all ordinary nuisances by the relieving officer.

10. That the district medical officer should report to the guardians all cases in which his instructions are not obeyed by patients, and that in the event of persistent disobedience Poor Law relief should be withdrawn or the patient compulsorily removed to hospital.

11. That, in determining the conditions under which pauper children should be reared, institutional life should be avoided as much as possible, and that when the mother is a widow she should receive money-relief sufficient to enable her to feed her children and keep them and the dwelling clean; but that if the mother is drunken, immoral, or incompetent, the children should be taken from her.

RECONSTITUTION.

Dr. McVail describes, and obviously prefers, a scheme for the reconstitution of Poor Law medical relief under an authority which should not only give medical relief in destitution, but would also take charge of all other public medical duties, so that its primary object would be not relief of destitution, but preservation of bodily and mental health and the prevention and cure of disease. He would reorganize the whole sanitary service in rural England, constituting local authorities with larger areas, whose main policy it would be to maintain the health of those committed to their care and to diminish the need for the cure of disease and the prescribing of drugs, but in whose functions the treatment of disease in paupers would be included. In addition to the duties now ordinarily discharged by a public health authority, it would have under its direction district medical officers whose duty it would be not merely to cure or palliate, but to prevent disease. Such an authority would have a principal medical officer, but Dr. McVail does not suggest that all such officers should be medical officers of health, believing that "for much of the supervising work a clinician might be better than a sanitarian." He, however, thinks that it would be necessary to require the district medical officers to possess an acquaintance with the preventive side of medicine. In favour of this scheme he argues: (1) That the healthy rearing of pauper children from their earliest years is a duty more suited for a health than for a Poor Law body, and that, as the officers directly engaged in this work would be the district medical officers, "supervision over them could best be exercised by a health authority having the benefit of skilled medical advice." (2) "That the control of pauper phthisis and phthisical families and their houses should certainly lie with the health authority." (3) That "almost every disease can be dealt with from the standpoint of prevention," and that "the early stages of disorders of all organs of the body—heart, lungs, kidneys, digestive system, brain, and the rest, often furnish indications for preventive measures." (4) That if the care of sick paupers were handed over to a health authority, some of the rural workhouses might be converted into hospitals for acute diseases, or surgical hospitals, into which persons requiring institutional treatment would be more willing to enter than into a workhouse.

There would then be left to the Poor Law authority only the relief of destitution, and Dr. McVail asks whether this also might not be handed over to the new health authority he has imagined.

MEDICAL PROVIDENT INSTITUTIONS.

In his memorandum on this subject Dr. McVail first discusses the advantages and disadvantages of a free medical service. The chief advantage is, he says, that "free access to, and acceptance of, medical advice on the part of the general community would certainly result in great improvement in average physical health and great diminution in the prevalence of disease," but he rejects the suggestion for reasons which had best be given in his own words:

If free medical attendance should be provided out of the rates because in itself it would be useful in improving the health of the community, medicines, of course, should be similarly provided. But in the treatment of disease it is hard to distinguish between food and medicine, so that an individual requiring the one out of the rates would similarly be provided with the other. And good clothing also has a bearing on health, so likewise has good housing and suitable employment, and a regular holiday in summer, and freedom from worry of all kinds. In short, the vista which is opened up by the suggestion of free medical service is practically endless.

He recommends in place of this the institution of a system of universal medical provident institutions. To these institutions the State should contribute, and thereby acquire a right to take part in their management and prevent abuses. He suggests that a list should be formed of medical men attached to each institution; and although the points are not specifically mentioned, would seem to assume that every medical man in the district should be eligible to serve, and that each member of the institution should have the right to select his medical attendant. He suggests that the controlling body of each provident medical institution should have the right of revising the list of medical men from time to time, and that the payment of the doctor should be by an annual fee for each member on his list. While admitting the impossibility of making membership compulsory, Dr. McVail considers that the inducements to voluntary membership would be threefold:

The State subsidy would be a direct attraction. Intelligent people of limited means would be very willing to contribute their moiety in order to get the benefit of the State's moiety. In the second place, the adoption by the new health authorities of a firm policy of refusal to grant medical relief to persons able to maintain themselves would indirectly promote the success of medical provident institutions. In the third place, the inherent value of the institutions would be apparent even at the beginning, and would quickly become more apparent as the result of experience.

He believes that if a general system of State medical provident institutions were established the friendly societies might discontinue medical attendance and medicines during illness, and that sooner or later outpatient departments of hospitals, except certain special departments requiring the use of expensive apparatus, would disappear.

The great difficulty, of course, comes when it has to be suggested how to deal with the person who will not voluntarily become a member of a provident institution. Upon this point Dr. McVail makes the following observations:

Supposing that a casual labourer, owing to illness and unemployment, required for himself and his dependants money relief from the Poor Law, and required, at the same time, medical attendance to be provided by the health authority, it might be arranged that the latter relief be given through the agency of a medical provident institution, the services of one of its officers being obtained, and a payment in respect thereof being made to the funds of the institution by the health authorities responsible for the medical attendance. If the patient were better removed to a hospital or infirmary, and if the health authority possessed such an institution of its own—say a transformed workhouse—the man would be sent there. Otherwise he might be sent to a voluntary hospital, and his treatment paid for by the health authority.

HOME MEDICAL INSPECTION.

The final memorandum contains a justification of the frequent references to preventive medical work in relation to the individual and the family. After enumerating the duties which, under this conception of the scope of the medical profession, Dr. McVail would assign to the district medical officer, he sums up as follows:

The medical man, in short, would be the family physician, not merely attending on acute illness, but taking charge of the general physical health and well-being of those who had placed themselves under his care. The prescribing of drugs would be the merest incident in his work, instead of, as is too often the case at present, its principal feature; and the time, both of the doctor and his clients, would be far more profitably occupied in the former way than in the latter.

MEDICAL INSPECTION AND AFTER.

LONDON.

MEDICAL INSPECTION.

THE London Education Committee, at its meeting on March 17th, adopted and referred to the County Council a report on the medical inspection of school children, stating that it had adopted a modified scheme. The Education (Administrative Provisions) Act, 1907, imposed the statutory obligation to provide for the medical inspection of school children immediately before, or at the time of, or as soon as possible after, their admission to a public elementary school, and on such other occasions as the Board of Education might direct.

The modified scheme adopted by the London Education Committee provides that the complete inspection of every child admitted to or leaving school shall be carried out in a limited number of schools (40 schools), while in a further limited number of schools (40) every child admitted for the first time, or who is about to leave school, shall be inspected; the records taken in these schools will not be so elaborate as those prescribed by the regulations of the Board of Education. In the remaining schools—that is to say, in the large majority—individual examination will only be made in the case of children presenting some abnormality, by which we understand that only those children will be medically inspected as to whom the teachers or other officials of the school suspect that they are abnormal. This modified scheme for medical inspection has been submitted to the Board of Education, and the Board in giving its approval refrained from insisting upon its full requirements being carried out in respect of every child at present, but added it must not be forgotten that, in considering the adequacy of such proposals, the Board will not be able to adopt the same standard of efficiency as they feel justified in applying to a scheme of an initiatory character.

With regard to communicating the fact of the necessity of medical treatment to parents, and to inviting their attendance, as well as that of teachers, at the inspection, the Committee made the following recommendations:

We propose that, in cases where the school doctor is of opinion that medical treatment is necessary a notice shall be sent to the parents or guardians informing them of the nature of the affection from which the children are suffering and advising them to consult a doctor; and that the parents shall be encouraged to attend the inspection in cases where individual children are examined. We think also it would be an advantage for the teacher of the class concerned to be present on these occasions, as the teacher would be in a position to give the school doctor helpful information, and the doctor would be able to give useful information to the teacher. We have accordingly had a form prepared notifying parents of the date of the visit of the school doctor and inviting their attendance. We have also approved the following letter to be sent to the teachers:

The Council is required by Section 13 (1) of the Education (Administrative Provisions) Act, 1907, to arrange for the medical inspection of children attending public elementary schools at such times as the Board of Education may direct. Each child admitted to school for the first time or who is about to leave school is to be medically inspected. For this purpose the school doctor will visit your department on the _____, and I shall be glad if you will grant him the necessary facilities for carrying out the work. Will you be good enough to place the following information in regard to each child on a medical record card: Name, address, date of birth, school department.

Before the doctor's visit a copy of form M 64 (inviting parents or guardians to be present) should be sent to the parent or guardian of each child to be examined. After the examination the doctor will supply you with a card M 49 (treatment card), for each child requiring treatment, to be forwarded to the parent or guardian. It is hoped that you will be able to arrange for the class teacher to be present at the examination in order that he may be able to obtain as much information as possible about his pupils.

The London County Council had this report before it at its meeting on Tuesday last, and its rejection was to have been moved by Mr. Jephson.

Mr. JEPHSON, however, withdrew his amendment, contenting himself with a protest against the "insufficiency" of the scheme.

The report was thereupon received.

MEDICAL TREATMENT OF SCHOOL CHILDREN.

The County Council also had before it the report, with appendices and notes, of the special committee appointed by the London Education Committee to inquire into the

question of the medical treatment of children attending public elementary schools in London.¹ In accordance with the Standing Orders of the Council, the report and recommendations had been considered by the Finance Committee of the Council, which presented the following report:

Report of Finance Committee.

"The Education Committee are submitting to the Council certain recommendations with reference to the medical treatment of school children. The report of the Education Committee treats the subject in a general way only, and no estimate is given of the probable expenditure to which the Council will be put in the event of a scheme being formulated on the lines indicated in the report. The only reference to cost is the statement that 'no provision has been made in the maintenance estimates 1909-10, but a sum of £5,000 has been included in provision money for the financial year in question.' The sum mentioned cannot, of course, be taken as any indication of the cost which the Education Committee anticipate would be involved in giving effect to the proposals which they indicate. The Education Committee are not, in fact, asking the Council to adopt any specific proposals, but only to express its opinion upon important questions of principle—obviously as a preliminary to taking further action and presumably formulating a more definite scheme. It is clear that the possibilities of expenditure for medical treatment of children in the elementary schools are great, even if limited to the specific classes of ailment to which the Education Committee specially call attention—namely, affections of the teeth, eyes and ears, ringworm and favus. It is quite impossible for us to give any information as to the cost of the proposals which are foreshadowed by the recommendations of the Education Committee. Full estimates must be laid before the Council before any definite scheme for the treatment of children is submitted, and we have communicated to the Education Committee a list of the points upon which, in our opinion, information should be furnished in connexion with any such scheme.

"The question of medical treatment has been under consideration for some time, but the position has, in our opinion, recently undergone a considerable change. The Prime Minister, on March 18th, 1909, received a deputation from local education authorities of England and Wales, together with members of Parliament invited by the local education authorities within their respective constituencies, with reference to the cost of national education and the necessity for an increased grant from the Imperial Exchequer. On that occasion the Prime Minister, dealing with the further educational burdens recently imposed upon local authorities, said:

As regards the last two, medical treatment and feeding of children, as you all know, they are optional and not compulsory burdens... that is to say, it rests entirely in the discretion of the local authority, having regard to local conditions and local requirements, whether or not they shall be incurred.

"Moreover, no hope was held out by the Prime Minister or by the Chancellor of the Exchequer, who also addressed the deputation, of any increased grant being made at present from Imperial funds in connexion with medical treatment.

"It seems to us, therefore, that the first question which the Council is called upon to decide is the broad question of principle whether or not, having regard to the Prime Minister's statement and the present and prospective burdens on the rate, the Council should, in the absence of any grant in respect thereof from the Imperial Exchequer, undertake the optional duty of medically treating school children; and the Council should, in our opinion, take the opportunity afforded by the Education Committee's recommendations to settle this general question. A further subsidiary question is whether or not the Council should undertake the duty of supplying medical treatment in any form unless power is given to the local education authorities to recover the cost of treatment from the parents except in cases where it is shown that the parents are not in a position to pay. Such power already exists in connexion with the feeding of school children, and no difficulty ought, we think, to be experienced by the Government in passing a short Act giving similar power to local education authorities in connexion with medical treatment.

¹ See BRITISH MEDICAL JOURNAL, December 26th, 1908, p. 1563; and January 9th, p. 96.

"In connexion with the general question whether the Council should undertake the medical treatment of children it should be borne in mind that the education rate is rising, and that it must, under present conditions and in the absence of increased Government grants, continue to rise, this being due amongst other things to the automatic increases in teachers' salaries, the cost of feeding necessitous school children, the new duty imposed on the Council of the systematic medical inspection of all children in elementary schools, and other matters to which the Council is committed. It should also be remembered that pressure is being brought to bear upon the Council to increase its expenditure in connexion with education in various other directions, amongst which the question of a complementary superannuation scheme for teachers may be mentioned. The question which naturally arises is whether there is not a limit to the burden which the ratepayer should be called upon to bear in connexion with education, and whether, as between the many objects desirable in themselves, which go to make that burden unduly heavy, it will not be necessary for the Council to make a selection."

Mr. CYRIL JACKSON, Chairman of the Education Committee, in a speech which was listened to with close attention, emphasized the seriousness of the problem. It was to be regretted, he said, that so small a number of hospitals and institutions had replied to the inquiries of the Special Subcommittee, but he thought the hesitation was natural when the Council asked such questions for the first time. It was hoped to have shortly a conference of hospital chairmen and secretaries to discuss what could be done by the hospitals and what the Council could do to help them. He was bitterly disappointed that the Prime Minister had received their request for increased Exchequer grants for medical treatment so unsympathetically, but failing that, they must make a start and provide some treatment. He could not advise the Council to undertake full treatment, important and necessary as it was. Dental treatment was the more expensive, and the Council should take in hand ringworm, suppurating ears and eyes. Figures received that day went to show that there were 2,706 cases of ringworm in London schools. Mr. Jackson concluded with a word of commendation of dispensaries, which he thought were often unfairly attacked, and also said he hoped the Council would extend its interest to the benefit societies, which had done so much for the sick poor.

Mr. HAYES FISHER moved a long amendment which practically embodied the report of the Finance Committee, of which he is chairman. The amendment declared that the Council is of opinion that certain diseases of children should be treated, and referred it to the Education Committee to report as to the cost of treating each of the affections mentioned in their report, and as to the steps necessary to be taken to amend the Education (Administrative Provisions) Act, 1907, to enable the Council to recover the cost of medical treatment from parents able to pay. Mr. Fisher urged that if the Council knew what it would cost to treat each disease, it could make a selection. He did not say the Council would never treat the children's teeth, but it ought to wait until it had power to recover the cost from parents.

Mr. ERNEST GRAY seconded, and, in spite of cries of "Time," continued his speech until the hour when only unopposed business is taken. The Moderate Whips did not follow the course which is often taken, of moving "that the sitting be continued until the matter under discussion shall have been dealt with," so the debate was adjourned until the last meeting before the Easter recess. If the instruction is then carried the Education Committee will not meet to consider it for a month.

WARWICKSHIRE.

Dr. A. Bostock Hill has prepared a report to the Education Committee of the Warwickshire County Council upon the results of the medical inspection of school children during the last three months of 1908. The inspections were carried out by Dr. A. Hamilton Wood and Dr. W. H. Davison, the former examining 2,124 children and the latter 1,051. Of the total, 1,327 were found to be suffering from defects which necessitated

advice being given. In 342 cases bodily uncleanness was present to a marked degree, and in 592, or 16.7 per cent., verminous heads led to cards being sent to the parents. There were 626 children of whom each suffered from four or more serious teeth. The following defects were found: Enlarged tonsils, 291; adenoids, 129; defective vision, 265; defective hearing, 41; various ear diseases, 66; defective speech, 37; "murmurs" of the heart, 81; anaemia, 94; incipient consumption, 14; tuberculous disease other than consumption, 4; epileptics, 4; bronchial catarrh, 82; ringworm, 37; impetigo, 17; and other cases of disease, 63. Fifty-five mentally defective children were discovered. Dr. Bostock Hill describes the gratifying work done by the health visitors under his direction in seeking to remedy some of the worst cases revealed by the inspection.

LONDON WATER.

THE Third Report on Research Work presented by Dr. A. C. Houston, Director of Water Examinations, to the Board on Friday, March 26th, deals with the Storage of Raw River Water antecedent to Filtration. In the introduction he points out that the medical advisers of the Local Government Board have long held the view that "time" is to be regarded as an important element among conditions that in Nature combine to annul the vital activities of particulate matter causative of disease. In no direction, perhaps, is this "time factor" of higher practical importance than in the case of storage of impure river water. The work of the water examination staff of the Metropolitan Water Board has been largely devoted to investigating the question anew, with special attention to those tests which gauge the viability of excremental bacteria in water. It is now thought that the merely mechanical effect of storage—that which results in the sedimentation of many of the microbes originally present in water—is of far less importance than certain de-vitalizing processes which occur under storage and which involve the ultimate extinction of specific bacteria in the water *plus* its sediment. A practical outcome of experimental work on this subject is that dependence is now being placed more and more on experimental proof that the water reaching the filter beds is, as the result of adequate storage, in a reasonably "safe" condition antecedent to filtration. When the stored water results are satisfactory, this really constitutes a new and important element in the "safety" of the London water supply, for it means that, even if a breakdown in the filtering arrangements occurred, the quality of the water distributed to consumers, although possibly open to criticism on physical grounds, might yet be relatively (if not absolutely) innocuous. Systematic observations on the effect of storage of raw water were commenced in August, 1907, and the report under review deals with the twelve months ended July 31st, 1908. After consultation with the engineering staff of the Board, the following waters were chosen for study:

A. Raw Lee river water above the "intake" for waterworks purposes at Ponder's End. B. Lee stored water—that is, water fairly representative of the above raw Lee water after storage in the eastern district reservoirs in the Lee valley. C. Raw Thames river water at Hampton not far distant from the "intakes" for waterworks purposes of most of the Thames derived supplies. D. Chelsea stored water—that is, water fairly representative of the above raw Thames water after storage in the Chelsea reservoirs. E. Lambeth stored water—that is, water fairly representative of the above raw Thames water after storage in the Lambeth reservoirs. F. Staines stored water—that is, water fairly representative of the above raw Thames water after storage in the Staines reservoirs.

RESULTS.

The following is a summary of the results:

Thames Water.

About 50 per cent. of the samples of raw Thames water contained typical *B. coli* in one-tenth of a cubic centimetre. Of the Staines, Chelsea, and Lambeth stored water samples about 34, 43, and 16 per cent. respectively, contained no typical *B. coli* in one thousand times as much water, namely, in 100 c.c.m. Thus, the Lambeth stored water was about one hundred and the Staines and Chelsea stored water between one hundred and one thousand times less impure than the raw Thames water.

Lee Water.

Over 50 per cent. of the samples of raw Lee water contained typical *B. coli* in one-tenth of a cubic centimetre. As regards

the Lee stored samples, actually as many as 67.4 per cent. yielded negative results with 100 c.cm., and only 32.5 yielded positive results in that amount. Thus, the Lee stored water was over one thousand times less impure than the raw Lee water.

These results, says Dr. Houston, remarkable as observed facts, are still more remarkable in their indirect bearing on the question of the "safety" of stored water. For the harmless, or comparatively harmless, *B. coli* is, like the highly pathogenic typhoid bacillus, of intestinal outcome. Moreover, *B. coli* is more resistant to unfavourable surroundings than the virulent microbe of typhoid fever. It follows, therefore, that processes which lead almost to the extinction of *B. coli* should operate more powerfully still on less robust germs of disease. Further, it is hardly conceivable that in any set of circumstances the typhoid bacillus would ever be present in any considerable bulk of the raw river water in anything like the same proportion as *B. coli*. In a previous report it was shown that if typhoid bacilli are added artificially in large number to raw river water, the great majority of them die within one week; and in a forthcoming report Dr. Houston says it will be shown that the death-rate of the cholera vibrio is, under parallel conditions of experiment, still more rapid. Further, in a separate report it has been shown that a prolonged search for the typhoid bacillus in the raw river waters yielded negative results. Hence, although we are without proof of the absence of the typhoid bacillus from these raw river waters, there is a strong presumption that it cannot be uniformly present in them unless in extremely sparse numbers.

It has been pointed out in previous reports that, apart from the question of the actual number of typical *B. coli* in the raw and filtered waters, there is a wide difference between the proportion of typical and non-typical *B. coli* in the two kinds of water. Thus, on the average, and dealing with the twelve months ended March 31st, 1908, out of every 100 coli-like microbes isolated from the raw and filtered waters 81.6 and 54.4 respectively proved to be typical.

The salient points resulting from the inquiry are summarized as follows: Taking the Lee results (averages) as an example, it may be said that the advantages of using stored Lee water as compared with raw Lee water would be: Over 97 per cent. reduction of the total number of bacteria capable of growing at blood heat, and of the bacteria able to grow in a bile-salt medium (chiefly excremental microbes). A one thousand-fold reduction in the number of typical *B. coli*. Dr. Houston's inferences thereon are: That a raw water which has uniformly undergone such a remarkable metamorphosis is almost certainly incapable after filtration, possibly (perhaps even probably) antecedent to filtration, of causing epidemic disease. Nevertheless, he regards storage of water as a prefiltration precaution of the utmost value, but not as a substitute for filtration.

ALTERNATIVE MEASURES TO STORAGE.

After discussing the results of chemical examination and the shape, size, depth, construction, and method of working storage reservoirs, Dr. Houston briefly considers measures for the improvement of London's water supply that may be regarded as alternative to storage. On biological grounds the only possible alternative to storage would, in his opinion, be sterilization. Having regard to the necessity of storage (for purposes of quantity apart altogether from questions of quality) to filtration in utilization of existing plant and to the epidemiological history of the metropolis, the wholesale sterilization of London water seems to him to be, on available evidence, economically out of the question, and therefore impracticable.

DISADVANTAGES OF STORAGE.

Although it would be wrong to infer that storage often, or habitually or necessarily, creates conditions inimical to filtration, there is inevitable danger that prolonged storage, especially if the water remains stagnant, may lead to the abnormal development of vegetable growths, materials harmless in themselves, but resulting in the deterioration of the water as judged by chemical and physical standards, and causing practical difficulties with its filtration. A possible disadvantage of using stored water is that the "blanket" or "skin" which forms on the surface of the sand in the filter beds may not

prove so effective a bacterial filter as that resulting from the use of raw river water. There may, Dr. Houston thinks, be an element of truth in this contention; but it is certain that sometimes the "stored-water skin" errs on the side of being too impervious, and it is obvious that it is much less important to have a microbe-tight blanket when using comparatively safe stored water than when using potentially dangerous raw river water. His experience since 1905 of the quality of filtered water supplied to East London from the East London (Clapton) Works, which deals, after prolonged storage, with the initially unsatisfactory Lee river water, does not lead him to think that this question of "stored-water skin" versus "raw-water skin" need necessarily be of vital importance.

ADVANTAGES OF STORAGE.

By far the strongest plea in favour of storage is based on the belief that adequately stored water is probably incapable of causing epidemic disease. No supersession, however, of filtration is suggested by Dr. Houston; his plea is for storage plus filtration. Assuming that an adequately stored water can be accepted as epidemiologically "safe," he would be satisfied if such water were passed through mechanical filters at an exceptionally rapid rate with a view to sending the water thus dealt with directly into supply. These mechanical filters, unlike sand filters, can be rapidly cleaned and put into operation again, which would be a great advantage in such circumstances. Another strong plea in favour of storage is the establishment of a continuous sense of security. If the results of the examination of such samples showed, from time to time, that the water had undergone the "changes" which in Dr. Houston's opinion point to "epidemiological safety," a lasting sense of security would as a consequence be established, and this irrespective of subsequent or final filtration. Another argument in favour of storage is that it tends to wipe out the gravity of the charge that London's water supply is derived chiefly from sewage-polluted rivers.

The chief points in favour of the storage of raw river water are summed up by Dr. Houston as follows:

- (1) It reduces the number of bacteria of all sorts.
- (2) It reduces the number of bacteria capable of growing on agar at blood heat.
- (3) It reduces the number of bacteria capable of growing in a bile-salt medium at blood heat, chiefly excremental bacteria.
- (4) It reduces the number of coli-like microbes.
- (5) It reduces the number of typical *B. coli*.
- (6) It alters certain bacteriological river-water ratios—for example, it reduces the number of typical *B. coli* to a proportionately greater extent than it reduces the number of bacteria of all sorts.
- (7) Storage, if sufficiently prolonged, devitalizes the microbes of waterborne disease—for example, the typhoid bacillus and the cholera vibrio.
- (8) It reduces the amount of suspended matter.
- (9) It reduces the amount of colour.
- (10) It reduces the amount of ammonia and nitrites.
- (11) It reduces the amount of oxygen absorbed from permanganate.
- (12) It usually reduces the hardness and may reduce or alter the quality of the albuminoid nitrogen.
- (13) It alters certain chemical river-water ratios—for example, the colour results improve more than the results yielded by the permanganate test.
- (14) It has a marked "levelling" effect on the totality of water delivered to the filter beds.
- (15) Storage tends generally to lengthen the life of the filters.
- (16) Under exceptional conditions is the converse true.
- (17) An adequately stored water is to be regarded as a "safe" water, and the "safety change" which has occurred in a stored water can be recognized by appropriate tests.
- (18) The use of stored water enables a constant check to be maintained on the safety of London's water antecedent to and irrespective of filtration.
- (19) The use of stored water goes far to wipe out the gravity of the charge that the chief sources of London's water supply are from sewage-polluted rivers.
- (20) The use of adequately stored waters renders any accidental breakdown in the filtering arrangements much less serious than might otherwise be the case.
- (21) The habitual use of stored water would lighten the grave responsibilities of the Water Board as regards the safety of the London water supply, and would tend to create a sense of security amongst those who watch over the health of the metropolis.

CONCLUSION.

After discussing in detail the length of time a water should be stored, Dr. Houston's final conclusion is that raw river water should be stored antecedent to filtration, preferably for thirty days. The question of whether the thirty days' storage should be fixed on a maximum or on a minimum basis must be left unanswered; but, if the former alternative be chosen, the desirability of employing supplementary processes of water purification to tide over emergencies is worthy of consideration.

The Water Examination Committee, in presenting the

report, stated that in its opinion the results of these investigations clearly proved that the policy of storing all raw river water antecedent to filtration was sound, and they felt that the habitual use of stored water lightened the grave responsibilities of the Water Board as regards the safety of the London water supply, and tended to create a sense of security amongst those who watched over the health of the metropolis. The desirability of considering whether supplementary processes of water purification, such as mechanical filters, precipitation tanks, etc., should not be employed to tide over emergencies was, however, a matter which merited attention in the future. The Board regarded the researches as not only of high scientific importance but also of great practical utility.

The report was adopted.

BRITISH MEDICAL BENEVOLENT FUND.

At the March meeting of the committee twenty-three cases were considered, and grants, amounting to £185, made to nineteen of the applicants. Appended is an abstract of the cases relieved:

1. Daughter, aged 45, of late M.D. Lond. Underwent serious operation about a year ago, and is unable at present to earn a living. Income only a few shillings a week. Relieved once, £5. Voted 25.
2. Widow, aged 54, of M.R.C.S. Eng., L.R.C.P. Edin. Quite unprovided for at recent death of husband. One child, 44 years. Hopes to obtain a situation as housekeeper, but health has suffered greatly from nursing her husband during the two years' illness which preceded his death. Voted £10.
3. Widow, aged 55, of L.S.A. No income; eight children, but only able to give slight help. Proposes to move, so as to decrease her rent. Relieved ten times, £115. Voted £5 for moving.
4. Widow, aged 62, of L.F.P.S. Glasg. No income; four children, but none able to help at present. Used to let lodgings. Voted £12.
5. Widow, aged 38, of M.P., Ch.B. Left quite unprovided for a few months after marriage, and lives with her mother, aged 72, who can ill afford to help. Health at present too indifferent to allow of permanent occupation. One child, aged 4 years. Voted 25.
6. Daughter, aged 50, of late M.D. Aberd. Has supported herself for many years by giving music lessons, but finds increasing difficulty in obtaining pupils. Is in bad health, and ordered to take a rest. Voted 26.
7. Daughter, aged 44, of late L.R.C.P. Edin. Used to be a dressmaker, but employers retired from business, and applicant has found it impossible to get regular work since. A little help from a friend, and earns as much as possible by sewing. Relieved four times, £40. Voted 26.
8. Widow, aged 60, of L.R.C.S., L.R.C.P. Irel. Lost everything through the failure of a bank, and is now in a very precarious state of health. No income; helped by a sister, who herself has to earn a living. Relieved twice, £24. Voted £12.
9. Widow, aged 59, of L.S.A. Lets lodgings; five children, but only able to give very slight help. Relieved seven times, £80. Voted £10.
10. Widow, aged 51, of L.R.C.P., L.R.C.S. Edin. Quite unprovided for at husband's death a few years ago. Obtains shelter as a caretaker, but receives no remuneration. No children. Relieved five times, £46. Voted £12.
11. Widow, aged 64, of M.D. Glasg. No income, and for several years has been practically dependent on this Fund and the Ladies' Working Guild. Relieved nine times, £104. Voted £10.
12. Widow, aged 50, of M.R.C.S. Eng., L.R.C.P. Edin. Kept a boarding-house and nursed her husband for several years previous to his death, but is now in such bad health that she is entirely dependent on her friends and a couple of sons who are only just self supporting. Relieved six times, £82. Voted £10.
13. Widow, aged 44, of M.R.C.S., L.R.C.P. Has a small annuity, but is in such bad health that it is insufficient for unavoidable expenses. Two children, aged 14 and 12. Relieved five times, £72. Voted £12.
14. Daughter, aged 54, of late L.F.P.S. Glasg. Unable to obtain regular employment on account of ill-health. Only income £10 a year from the Scottish Indigent Gentlemen's Fund. Relieved twice, £24. Voted £12.
15. Widow, aged 48, of M.R.C.S., L.S.A. No income; endeavours to support herself by needlework and receives a little help from friends. Two children, aged 22 and 15. Relieved six times, £71. Voted £12.
16. Daughter, aged 52, of late M.R.C.S., L.S.A. No income and is in very feeble health. Receives a little help from a sister. Relieved eleven times, £125. Voted £12.
17. Widow, aged 68, of M.D. Aberd. No income. Children unable to help; a little assistance from friends. Relieved eight times, £102. Voted £12.
18. Daughter, aged 60, of late M.R.C.S. Had a post as companion but was obliged to give it up to nurse two sisters who have since died. Hopes to obtain boarders and is made a small allowance by a relation. Relieved twice, £30. Voted £12.
19. Widow, aged 51, of M.D. Edin. No income; children help as far as possible and applicant earns a little by needlework. Relieved three times, £30. Voted £10.

LITERARY NOTES.

In an article in the *Cornhill Magazine* for April, the Rev. P. H. Ditchfield discusses the mind of the rustic with the insight born of knowledge mingled with sympathy. His experience of the tendency of the countryman to fall into the toils of quacks will doubtless be confirmed by many of our readers. He says:

In spite of his shrewdness, his cleverness, and accurate calculations of the amount due to him for wages, the rustic often falls an easy prey to quacks and impostors. The good gentlemen who undertake to cure all manner of diseases find agricultural labourers some of their best customers. Quack remedies, patent medicines, wonderful oils for curing rheumatism, the bane of the rustic, are eagerly bought, and large sums are wasted out of scant earnings for the purchase of these amazing remedies. I have just seen a most insidious letter written by an American quack to a poor woman who was anxious to obtain a cure for her sick son. This quack has an agent in London who advertises remedies for the disease from which this boy suffers, as well as for many others, and sends a free bottle of medicine. This is followed by a long letter from the American, promising to cure the complaint, the cost of the treatment being £3, but he is obliging enough to say that he will only charge one pound in her case. The sample bottle, he states, was only a tonic, and was not part of the cure, but that if the money be paid, a complete cure will be effected. A ticket for the county hospital happily solved the difficulty, and one pound will not be added to the American quack's receipts. But quacks of other sorts exist nearer home, and some years ago in a neighbouring village a herbalist and astrologist gained a considerable reputation among the poor whom he duped as a "very clever man." A poor widow who was suffering from a simple form of ophthalmia had implicit confidence in him, until, getting no better and her funds being exhausted, she reluctantly fell back upon the parish doctor. She told him that she had got the black crab cancer in her eye, and that it was sucking her sight out, and that the wise man had informed her that the stuff to kill this monster would cost £2, and that what he had done already had much weakened him. A short time and simple remedies put her quite right; but she always maintained that "twas the wise man as first poisoned the black crab cancer." The poor folk had generally a firm belief in his powers, though it would have been difficult to find a single cure that he had effected.

A second edition of Professor Karl Pearson's Robert Boyle Lecture on the Scope and Importance to the State of the Science of National Eugenics, which was delivered before the Oxford University Junior Science Club on May 17th, 1907, has recently been issued as No. 1 of a series of papers dealing in non-technical language with the problems of eugenics. It is an introduction to the science of eugenics for the study of which Mr. Francis Galton founded a laboratory at University College, London, with the objects that it should serve as a storehouse of statistical material bearing on the mental and physical conditions in man, and the relation of these conditions to inheritance and environment; as a centre for the publication or other form of distribution of information concerning national eugenics; and as a school of training and assisting researchers in special problems in eugenics. Among the publications that have so far appeared are *The Inheritance of Ability*, by Dr. Edgar Schuster and Miss Ethel M. Elderton; *A First Study of the Statistics of Insanity and the Inheritance of the Insane Diathesis*, by Mr. David Heron; *The Promise of Youth and the Performance of Manhood*, by Dr. Edgar Schuster; *On the Measure of the Resemblance of First Cousins*, by Miss Ethel M. Elderton, assisted by Professor Karl Pearson; and *The Treasury of Human Inheritance (Pedigrees of Physical, Psychological, and Pathological Characters in Man)*. Two other publications which will appear shortly are *Influence of Parental Occupation and Habit on the Welfare of the Offspring*, by Miss Ethel M. Elderton, and *Influence of Unfavourable Home Environment and Defective Physique on the Intelligence of School Children*, by Mr. David Heron. The Eugenics Laboratory Publications are issued by Messrs. Dulau and Co., 37, Soho Square, London, W.

Thomas Dover has long figured in medical history as a doctor who, finding the practice of medicine too unexciting for his taste, sailed the Spanish Main as a buccaner. In an interesting article which appeared in the *Eristol Medico-Chirurgical Journal* for March, Dr. J. A. Nixon endeavours to show that this is a legend, and that Dover was not a buccaner but a merchant adventurer. He says the expedition in which Dover sailed was not of a piratical nature; it was one of those adventurous trading cruises of which Hakluyt in *Principal Voyages of the English Nation* gives many instances. Men who embarked on such

enterprises at the beginning of the eighteenth century had indeed to be ready to defend themselves against attack by Spanish or French vessels, and fighting was a common experience. The voyage round the world of two privateers, the *Duke* and *Duchess*, under the command of Captain Woode-Rogers, was a properly accredited enterprise of the merchant adventurers of Bristol. Dover, who was a man of means, had a share in the risk, and was selected to represent the Owners' interest, and sailed on the *Duke* as second captain under Woode-Rogers and captain of the mariner. He presided over all councils in which he had two votes; and his share of all profits was calculated in thousands to the hundreds of the other senior officers. Ample provision was made for the medical welfare of the expedition. In addition to Dover, there sailed John Ballet, rated third mate, but designed surgeon in case of need (he had been Captain Dampier's doctor in his last unfortunate voyage); James Vigor; James Wasse, surgeon; Charles May, his mate; and John Lang, assistant. Then there was an apothecary, Samuel Hopkins, Dover's brother-in-law. Nevertheless, Woode-Rogers says the surgeons complained of the want of sufficient medicines. Dover's interest in the undertaking seems to have been commercial rather than medical. He was an extremely cantankerous member of the expedition, and when a prize was taken claimed, as second in command, to take command of her. Against this the navigating officers protested, on the ground that he was utterly incapable of the office. He had his way, however, as far as the titular command was concerned, but he was forbidden to interfere in any way with the navigation of the ship. As a physician Dover had been well trained. He was a B.A. of Oxford and M.B. of Cambridge. He practised for a time at Bristol, being the first medical man who offered his services gratuitously on behalf of the poor under the care of the guardians of the city. This was in 1696. In 1709 he sailed as Captain Dover on his famous cruise, in the course of which he discovered Alexander Selkirk, the original of Robinson Crusoe who had been marooned on the island of Juan Fernandez. At a later period Dover resumed the practice of his profession in Gloucestershire and finally in London. From his belief in the sovereign virtues of mercury he was known as the "quick-silver doctor," and he was the inventor of the *Pulvis Ipecacuanhae Co.* which bears his name. His violent temper made him unpopular among his brethren, whom he amiably described as "a set of gentlemen, who, likewise, work underground, lest their practices be discovered to the populace." He was the author of a popular work, entitled *The Ancient Physician's Legacy to His Country*, which "made a great noise in London, and was the subject of almost every Coffee-house." He hated apothecaries almost as heartily as Gui Patin, and accused them of inflating bills for treatment of a fever to forty, fifty, or sixty pounds. Whether Dover was a buccaneer or a respectable "adventurer," it appears to be certain that he returned from his expedition, which lasted from 1708 to 1711, a wealthy man. The expedition sacked the two cities of Guayaquil, Dover leading the van. They took several prizes and cruised about the coast from Peru to California on the look-out for treasure ships. But this, according to the ethical standard of the day, was legitimate commercial enterprise.

Medical News.

A PROPOSAL that immunization against typhoid by vaccination should be introduced is said to be under consideration by the United States Army authorities.

MR. JAMES CANTLIE, F.R.C.S.Eng., has been promoted from Honorary Associate to be Knight of Grace of the Order of the Hospital of St. John of Jerusalem in England.

THE Orient Steam Navigation Company's new twin-screw steamer *Otranto* (2,000 tons), launched at Belfast on March 27th, is to go three pleasure cruises to Norway in July and August before being placed on the mail line to Australia.

At the sessional meeting of the Royal Sanitary Institute to be held at the Parkes Museum, Margaret Street, W., on Wednesday next, Mr. W. D. Scott-Moncrieff will open a discussion on river pollution, its ethics, aesthetics, and

hygiene. The chair will be taken by Sir Francis Sharp Powell, M.P., at 8 p.m.

AN appropriation of £2,000 for the care of tuberculosis patients has been approved by the New York Board of Aldermen. The money will be used to fit up two old ferryboats so that they may be used as general tuberculosis hospitals.

SIR GEORGE KING, K.C.I.E., M.B., F.R.S., LL.D., formerly Superintendent of the Royal Botanical Gardens, Calcutta, who died on February 12th, has bequeathed a bronze medallion portrait of himself to the University of Aberdeen. Similar medallions are left to the Linnean Society, London, and to Colonel D. D. Cunningham for life, with remainder to the National Portrait Gallery, Edinburgh.

THE eighth international Conference on Tuberculosis will, as already announced, be held at Stockholm from July 8th to 10th. The programme includes the following questions proposed for discussion: (1) Precautions to be taken in tuberculous families, especially for healthy children. (2) Report of the Sanatoriums Commission. (3) The use of specific agents in the diagnosis and treatment of tuberculosis. (4) Tuberculosis in schools. (5) Miscellaneous addresses. (6) Report on the progress of the campaign against tuberculosis in various countries.

DR. F. W. MOTT, F.R.S., will give two lectures on the brain in relation to right-handedness and speech at the Royal Institution of Great Britain on April 20th and 27th; Dr. W. H. R. Rivers, F.R.S., will give two lectures on the secret societies of Banks' Islands on May 22nd and 29th; Dr. F. Gowland Hopkins, F.R.S., two lectures on biological chemistry on June 1st and 8th; and Dr. F. F. Blackman, F.R.S., two lectures on the vitality of seeds and plants on June 5th and 12th: all these lectures will be given at 3 p.m. At the Friday evening meeting on May 7th Major Ronald Ross, C.B., F.R.S., will deliver a lecture on the campaign against malaria, at 9 p.m.

DR. P. MACRY DEAS, who has been for twenty-five years Medical Superintendent of the Wonford House Hospital for the Insane, Exeter, and who before that was for fifteen years Medical Superintendent of the Parkside County Asylum, Cheshire, is about to retire, and will carry with him the good wishes of his colleagues, and in particular the gratitude of the members of the profession in the south-west of England, whom he represented for many years on the Central Council of the British Medical Association. Dr. Deas will be succeeded by Dr. W. Britain Morton, who for the last twelve years has been the chief medical officer of Brislington House, Bristol, and was formerly assistant medical officer at Wonford House.

THE ninth meeting of the Departmental Committee appointed by the Lord President of the Council to consider the working of the Midwives Act was held at the Privy Council Office on March 31st, Mr. Almeric W. FitzRoy, the Clerk of the Council, presiding. The following witnesses attended and gave evidence: Sir Shirley F. Murphy, Medical Officer of Health of the County of London, on behalf of the London County Council; Mrs. Swinton, Matron of the Buckingham Palace Road Workhouse of the St. George's (Hanover Square) Union, on behalf of the National Association of Workhouse Masters and Matrons; Dr. Edward Sergeant, County Medical Officer of Health, Lancashire, on behalf of the Incorporated Society of Medical Officers of Health, and of the Midwives Act Committee of the Lancashire County Council.

THE usual monthly meeting of the Executive Committee of the Medical Sickness, Annuity, and Life Assurance Society was held at 429, Strand, London, W.C., on March 19th, Dr. de Havilland Hall in the chair. The record of the business of the society during the early part of this year is satisfactory. The number of sickness claims received has been large, but this is expected at this season of the year, and so far, the amount of sickness experienced compares favourably with the records of the same period of last year. The number of new entrants has been much above the average though not quite equal to the record of 1908. The rapidly-growing number of those members who have increased the assurances they originally effected with the society shows how useful the sick pay is found to be. Numerous letters are received showing how valuable the sick pay, usually £4 4s. a week, is to those who are only temporarily incapacitated, while to those who have no hope of ever recommencing professional work and who for the most part draw an allowance of one hundred and four guineas a year, this continued sick pay is in all cases a valuable assistance and, in some instances, the only bar to actual privation. Prospectuses and all further particulars on application to Mr. F. Addiscott, Secretary, Medical Sickness and Accident Society, 33, Chancery Lane, London, W.C.

British Medical Journal.

SATURDAY, APRIL 3RD, 1909.

ADMINISTRATIVE MEASURES AGAINST TUBERCULOSIS.

As already stated briefly, the Memorandum by the Medical Officer of the Local Government Board on Administrative Measures against Tuberculosis, 1909, which was issued recently, is intended to supplement from a medical standpoint the circular letter issued by the Local Government Board with the Public Health (Tuberculosis), 1908, Regulations. It explains and to some extent amplifies these regulations, for though the order was primarily intended only for patients under the care of Poor Law medical officers, the suggestions contained in this Memorandum are of wider application. It is pointed out that all public health administration in relation to tuberculosis, whether in poor persons or others, is concerned with similar problems, and as "poor" persons frequently pass outside the scope of the Poor Law, and as the regulations will in many districts be worked alongside a system of voluntary notification of tuberculosis, it is undesirable to limit the scope of the Memorandum strictly to poor patients.

The Memorandum briefly summarizes the preventive measures desirable in all cases of pulmonary tuberculosis, and indicates the lines to be followed in order to achieve the results aimed at. The question is discussed in a temperate and judicial manner, and the necessity for tact in carrying out administrative action is wisely insisted upon.

In considering the characteristics of tuberculosis which furnish the key to preventive measures, emphasis is laid on the limited sources of infection and the ease with which these may be controlled, as also on the comparatively slight susceptibility of healthy human beings.

The Memorandum lays it down that tuberculosis must be looked upon as a disease of ignorance, and much stress is therefore laid on the importance of educational measures against the disease. As instruction of the patient is essential for the prevention of tuberculosis, it is the duty of the doctor immediately the disease is recognized to inform the patient, or his friends, as to the nature of the complaint, and to give instructions to the patient. He may also be acting in the interest of his patient as well as in that of the public health, in notifying the case to the medical officer of health under a voluntary system of notification, even though the case is not one which is compulsorily notifiable. In this way the medical officer of health may be enabled to furnish supplementary aid in disinfecting rooms or in other ways.

The importance of early diagnosis is insisted upon, and the value of bacteriological investigation as an aid to diagnosis is pointed out, though its limitations are also noted. When notification is made, the visit to the case reported may often afford an opportunity of procuring the examination of others who have been in close and continuous contact with the patient, and in this way cases may be discovered at an early stage.

The possibilities in this direction which the systematic examination of school children presents is also pointed out.

One very important feature of the Memorandum is that dealing with the procedure in official investigations; its tone will be widely appreciated, for it points out that inquiries should be tactfully made, and that the advice offered must not interfere with that given by the doctor in attendance. Above all, care must be taken that nothing shall be done that may prevent a consumptive from continuing to earn his livelihood. In certain cases repeated visits may be necessary to ensure that the patient is carrying out instructions. If the spirit of this Memorandum is fully carried out, the co-operation of the medical officer of health would frequently be of great assistance to the doctor in attendance and of benefit to the patient.

The Memorandum concludes with a summary of the chief aids to preventive measures, in the institutional treatment of consumptive patients, dispensaries for consumptives, sanatoriums, and homes for advanced cases.

As a whole the Memorandum is a valuable summary of the measures necessary in the prevention of consumption, and should prove of value to many beyond those who have to treat patients under the Poor Law.

THE DIAGNOSIS OF FUNCTIONAL PARALYSIS.

ANY aid to the differential diagnosis of functional paralysis is to be welcomed in the present day, when recent legislation has placed a premium upon malingering and medical men are asked to express opinions on cases which are not under the most favourable conditions for close observation, and cannot always be subjected to the rough tests by which it is sometimes possible to demonstrate the unreal nature of alleged paralyses. Babinski has shown that if a patient with organic hemiplegia is placed upon a high seat so that his legs hang freely, the paralysed leg is extended on the thigh when he folds his arms tightly, or if he is lying down and tries to raise himself into a sitting position with the arms crossed on his chest, the thigh is flexed on the pelvis and the heel is raised from the ground. Finally, if the patient lies down with his legs hanging over the end of the bed, and then tries to raise himself into a sitting position the paralysed leg is extended on the thigh and the thigh is flexed on the pelvis. All these phenomena are absent in hysterical hemiplegia, and are exclusively observed in cases of organic origin. Three years ago Grasset and Gausse drew attention to another sign, which is, that when a patient with organic disease is able to raise the paralysed leg from the bed, he yet cannot raise both lower extremities simultaneously. This is due to the need there is for fixing the pelvis in the movement of flexing the thigh. This fixation must be furnished by the healthy leg, and when the latter is raised, this is no longer possible, and the paralysed limb drops.

Dr. C. F. Hoover of Cleveland, who has studied this phenomenon from another standpoint,¹ says that when one leg is raised from the bed in a patient with an organic lesion the heel of the other is pressed hard against the mattress; this is very perceptible if a hand is placed under the heel. Conversely, if the patient presses the heel of the foot hard against the mattress, there is a slight raising of the opposite leg.

¹ *Journal of American Medical Association*, August 29th, 1908.

In cases of organic hemiplegia or crural monoplegia due to organic causes this "complemental opposition" on the side of the sound leg is never absent. In two patients who complained of a crural monoplegia following an injury Dr. Hoover was able to demonstrate by the absence of these symptoms that there was no real paralysis. When the patient was asked to raise the paralysed limb there was no pressure of the heel on the sound side, but when asked to raise the healthy leg, the paralysed limb contracted and pressed strongly against the bed. The same absence of the sign was noted in a case of hysterical hemiplegia when the patient was told to raise the paralysed limb.

Dr. P. Zenner of Cincinnati has confirmed² the observations of Dr. Hoover. In a young man with organic right-sided hemiplegia from a tumour of the pons, when the patient raised the left leg there was no movement of the other; but when he was told to try to raise the paralysed leg it did not move, but the left heel was dug into the bed. The second case was that of a woman, aged 23, suffering from hysterical hemiplegia and hemianaesthesia on the right side following a shock. When she was asked to raise the paralysed right leg there was no movement either of that leg or the other, but when she raised the sound limb the right heel was pressed into the mattress.

These observations have been further confirmed by Dr. J. Lhermitte.³ Having looked for the sign in normal persons and found it constant, he examined fourteen cases of organic hemiplegia in the Salpêtrière. At first he thought that it was absent in some old cases, but further investigation proved that this was due to the patients being too lazy to make the necessary effort, and on persisting he could always obtain distinct movement on the sound side. This movement seemed to be in proportion to the extent of the hemiplegia, and in those who had nearly recovered it was present to about the same extent as in healthy persons, while it could be made more manifest by resisting slightly the elevation of the paralysed limb. On the paralysed side the movement is naturally less developed than on the sound side and is always absent when the hemiplegia is complete; if it is spastic the sign is generally equal on both sides. Dr. Lhermitte examined two cases of hysterical hemiplegia, the first being a young woman, aged 21, who without apparent cause complained of a pain in the left hand which was soon followed by stiffness of the fingers and complete contracture of the left arm; a month later similar phenomena showed themselves in the lower extremity, the foot assuming a position of forced equino-varus, the leg being extended on the thigh and the thigh extended on the pelvis; the great toe was hyper-extended and its second phalanx flexed; the patellar reflexes were lively on both sides, but rather more on the paralysed side; the plantar reflex was flexor on the right but on the left tickling the sole of the feet determined no change in the position of the great toe. When the patient was told to raise the spastic limb, the movement being slightly resisted, there was energetic counter-pressure by the sound heel, and when the sound leg was raised there was exaggeration of the rigidity, and the heel was pressed firmly into the bed. This result pointed to an organic cause, but Dr. Lhermitte does not accept this conclusion, as he thinks the spastic condition interferes with the sign. In another case, where the hysterical paralysis was

flaccid, the test was valid; this was a patient aged 54, the subject of major hysterical attacks, in whom, hypnotic sleep having been induced, a right-sided hemiplegia was developed by suggestion. When lying flat the patient could easily raise the left leg, while all movement of the right side was impossible; if she was told to raise the paralysed limb there was absolutely no contraction in the muscles of the left leg, while, when she raised the left leg, the hand placed upon the right thigh perceived slight movements in the biceps and semimembranosus. Lhermitte meets the objection that hysterical hemiplegia so induced is not identical with ordinary functional paralysis by quoting Babinski's authority for the statement that hysterical paralysis may be reproduced by suggestion in some subjects who are hypnotisable, and that the identity of these two kinds of paralysis seems to show that the paralysis which occurs in hysteria has its origin in suggestion or autosuggestion.

The method of examination is easy, but wider experience is needed to show to what extent the test can be relied on as a basis for an opinion in medico-legal cases.

POSTAL OFFICIALS AND VACCINATION.

AN announcement has appeared to the effect that the Postmaster-General has modified the regulations of the service as regards vaccination. It is stated that in future candidates for Post-office employment who have conscientious objections to revaccination may be allowed exemption therefrom on making a statutory declaration to the effect that they conscientiously believe that revaccination would be prejudicial to their health. The Postmaster-General has refused to grant exemption from primary vaccination. If this accurately states the decision, a most unsatisfactory, and scarcely comprehensible, state of affairs is created. The antivaccinators who have clamoured for the removal of vaccination as a condition of employment will not be silenced or appeased by this change as a departmental answer to their deputation pleadings. This concession, even if it be regarded by the antivaccinators as a real concession, will be to them most unpalatable, since vaccination still remains a condition of employment. To those who are familiar with the evidence in favour of vaccination and revaccination, the decision will seem unfortunate, and the principle on which the ruling is based requires explanation. Evidence of the special risks of infection to which postal officials are exposed, and the protection afforded by revaccination, was given before the Royal Commission on Vaccination. The Final Report of the Commissioners states (par. 340) that Sir Charles Dilke, speaking in June, 1883, made the following statement about those employed in the postal service in London: "In the case of persons permanently employed in the postal service in London, averaging 10,504, who are required to undergo vaccination on admission unless it has been performed within seven years, there has not been a single death from small-pox between 1870 and 1880, which period included the small-pox epidemic, and there have only been 10 slight cases of the disease. In the telegraphic service, where there is not so complete an enforcement of vaccination, there have been only 12 cases in a staff averaging 1,500 men." The Commissioners, commenting on this, draw attention to the fact that many of the persons so employed become subject, in a degree exceeding that of the population at large, to the risk of contagion, and emphasize the fact that the period referred to in the evidence above given includes that of the epidemic

² Ibid., October 17th, 1908.

³ La Semaine Médicale, 1908, p. 565.

in London of 1870-2, when there were so many attacks and deaths from small-pox. "It is noteworthy," continues the report, "that, in the year 1892, 12 officers were absent from duty on account of the presence of small-pox in their homes; in 1893, 44; and in 1894 as many as 53." Possibly the Postmaster-General thinks the exemptions may not be sufficiently numerous to constitute a serious risk to the service, for it must be admitted that the presence of evidence of primary vaccination in the candidates for employment who are themselves healthy should tend to destroy the argument that revaccination would be prejudicial to their health.

THE INFLAMMABILITY OF FLANNELETTE.

THE question of the inflammability of flannelette has aroused a good deal of discussion lately among the public and in the press, and is at the present moment occupying the attention of the officials at the Home Office, who are carefully investigating the alleged dangers attached to this material. Flannelette, which is, of course, a cotton fabric, and not woollen at all, has the great advantage of being cheap and warm. It is an undoubted boon to the poor, who find it impossible to buy flannel on account of its cost. There is no substitute for it which gives the same amount of warmth, within reach of the purse of the poor. But it has the great disadvantage of being very readily inflammable. Methods have been suggested to minimize or do away with this dangerous quality of flannelette. The first of these is to soak the material in various chemical substances before it is sold, and the manufacturers claim that flannelette is rendered permanently flame-proof by this means. As a matter of actual experiment it is found that the chemical which impregnates the material is washed out, or loses its efficiency after a very few washings, and the fabric burns much more readily than it originally did, and in some cases as readily as ordinary flannelette. The cheapest variety of patent material costs 6½d. a yard; a cheap flannelette can be purchased for 2½d. or 3½d. a yard. Is it, then, reasonable to expect the working woman, whose income is reckoned in shillings, to pay this increased price for advantages so very fleeting and questionable? The second method, and one which is just now being much recommended, is to impregnate the material, at each time of washing, with chemicals which render it non-inflammable. Various substances are now on the market for which it is claimed that, for a very small sum and with very little extra trouble, the flannelette washed in them is rendered non-inflammable. Among the materials employed are borax, alum, oxide of tin, and patent preparations such as Flameoff, etc. The results of experiments with these various preparations show that some of them—for example, Flameoff and borax—are certainly effectual in very considerably reducing the inflammability of flannelette, others—such as alum—make very little, if any, difference. But the most serious objection to all these various chemicals is the fact that it is necessary to use them with each washing, and this alone—involving as it does extra trouble and expense—is sufficient to prevent their general employment among the poorer classes, where practically all the burning fatalities occur. Much more important than any special treatment of flannelette by chemicals or otherwise, useful as this may be as an additional precaution in diminishing deaths from burns in children, is the employment of some method for preventing fire reaching their garments, for *all* clothes, of whatever material, are inflammable—some, of course, like flannelette, much

more so than others. It is found that in about 85 per cent. of inquests on deaths from burning in children the absence of fireguards was a direct cause. In the new Children Act, which came into force on April 1st, there is a clause which imposes a specific penalty on a person in charge of a child under 7 years if, owing to neglect of reasonable precautions to guard an open fire, the child is seriously burned or scalded. It is to be hoped that this enactment may lead to the more universal adoption of protective fireguards and so save the lives of many valuable future citizens.

LIABILITY OF HOSPITALS.

THE question whether the governors of a hospital can be held liable at law for injuries sustained by a patient is by no means easy to answer. It must be shown, of course, that the injury sustained was the result of negligence, and that the act or omission which occasioned the injury was the act or omission of some person in the employment of the hospital authorities. The fact that the treatment is gratuitous does not appear to affect the question. In a case which is reported elsewhere in this issue, an action was brought to recover damages from the governors of St. Bartholomew's. The plaintiff, a medical practitioner, suffering from sciatica, went to the hospital to be examined under an anaesthetic. The examination was conducted by a member of the staff. It was alleged that while the patient was on the operating table his left arm was scalded by being brought into contact with a hot-water tin, and that his right arm was injured by pressure, and that in the result paralysis supervened to such an extent that he would never again be able to practise his profession. At the conclusion of the opening of the plaintiff's case it was submitted that the action did not lie against the governors, inasmuch as it was not shown that the injuries (if any) were caused by any one for whose acts they were responsible. Counsel for the plaintiff conceded that the governors were not responsible for the surgeon who conducted the operation, as he was not their servant. Mr. Justice Grantham decided to hear the evidence of the plaintiff and his witnesses, and having done so, came to the conclusion that there was no case to go to the jury. His decision was for the most part based upon the inconclusive nature of the evidence. He pointed out that there was no proof of negligence on the part of any one in particular, and he also dwelt on the fact that the patient was predisposed to the injuries sustained owing to the sciatica from which he suffered. The interesting legal question was not therefore authoritatively decided. There is no English case which throws any certain light upon it. In a recent work entitled *The Law of Hospitals*, by A. T. Murray, the author states that "a hospital is responsible to the patient for the negligent acts of its doctors or nurses in the course of their treatment of any such patient." He admits, however, that this is a mere expression of his opinion based upon cases relating to analogous points. In one case (Evans v. Liverpool) Mr. Justice Walton held that the authorities responsible for a rate-supported hospital were not liable because a member of the staff had allowed a scarlet fever patient to leave the hospital so soon that he communicated the disease to other children of the plaintiff. That decision was mainly based on the principle that a corporation which owns a hospital does not undertake the duties of medical men, or to give medical advice, but that the patients in their hospitals shall have competent advice and assistance. It was admitted that the doctor responsible for the discharge of the patient was a competent medical man.

There are certain American cases on the question, but as they conflict one with another they are of little value to an English lawyer.

SPIROCHAETES AND MOUSE CARCINOMA.

THE record of negative results is often of considerable value, for not only does a negative result, if confirmed, narrow the problem down, but it not infrequently indicates the direction in which further research may prove successful. Negative results have other uses. In a hopeless disease, the nature of which is still shrouded in darkness, the unfortunate victims too often catch at any straw, no matter how frail, which may be held out. The public is at all times credulous about remedies which have not obtained the support of the profession, and whether the reputed remedy is a secret quack preparation or a discovery of one day, the average patient suffering from such a disease as cancer will pin his faith on it, and allow the last hope—the hope of getting rid of his disease by surgical means—to fade away. But it is not only the devising of alleged cures which may be mischievous, but the supposed discovery of the cause of cancer, which has been made about once every two months for some years past, may be almost equally mischievous, for before it can be shown that the discovery is based on a false observation, either the discoverer or someone else builds up a treatment on this unstable basis. It is therefore of great value to learn of distinct negative results with regard to the possible causation of cancer. Professor Gaylord found a spirochaete in primary and transplanted carcinoma of the breast of the mouse in 1907. He now¹ comes forward in true scientific spirit and shows that this spirochaete has no etiological connexion with the malignant disease. The spirochaetes were found by Tyzzer in mouse tumours, and Deetjen has also found them in something approaching regularity in mouse carcinoma. Since his original publication Gaylord has examined a series of 48 tumours. In 4 of these the disease had advanced so far that contamination with other micro-organisms rendered the search fruitless. In 4 further tumours no spirochaetes were found, while in the remaining 40 they were found at the periphery of the tumour. He then turned his attention to other mice in the same breeding-places as the cancerous mice had come from, and found that out of a series of 10 no fewer than 7 harboured spirochaetes in their blood. In a second series of mice received from Columbia, 11 out of 15 showed spirochaetes in the blood. Other series yielded similar results. He was therefore able to determine that the spirochaetes were present in about 70 per cent. of apparently normal mice. He adds that the absence of spirochaetes in human cancer and in cancers of other animals, and the fact that several strains of transplantable mouse tumour have been examined in vain for spirochaetes, justify him in concluding that the spirochaetes are not the cause of mouse carcinoma. This conclusion appears to be sound, and may be advanced as a further argument against the parasitic theory of carcinoma.

PRIMARY PERITONEAL OR ABDOMINAL PREGNANCY.

ECTOPIC gestation is of special interest to the profession in general, rather because it is a cause of internal haemorrhage than on account of its peculiarities from an obstetrical or pathological standpoint. The labours of Lawson Tait and his experiences as an operator taught us that the Fallopian tube undergoes changes prejudicial to the

patient when it becomes the seat of pregnancy, and that in early pregnancy the bleeding or ruptured tube may be removed without much difficulty and with little risk. Tait believed that all ectopic pregnancies were originally tubal, from which it followed that early diagnosis and removal of the sac would save every case, though operations late in such pregnancies were, and remain, very hazardous. Kowler and Van Tussenbroek, followed by Anning and Littlewood, Octavius Croft, and others have shown on evidence accepted by leading authorities that ectopic pregnancy may begin in the ovary. The surgery of primary ovarian pregnancy, however, is little different from that of primary tubal pregnancy, for when early rupture occurs in either form both tube and ovary have to be taken away. The possibility of a primary peritoneal or abdominal pregnancy remains doubtful, and much further information is required, for while the amputation of a Fallopian tube with its fetal sac is not very difficult or dangerous in early pregnancy, a fetal sac sessile on the peritoneum would, theoretically, be very dangerous to remove almost from the first, as the operator could hardly feel sure how to control its blood supply. A case recorded recently by Gröné, of Malmö, Sweden, seems to show that primary peritoneal pregnancy may occur, and—what is of equal importance—that in its earliest stages at least its removal is neither difficult nor dangerous.¹ A woman aged 23 was admitted with symptoms of internal haemorrhage following colicky pains fourteen days earlier. The periods had been quite regular for four months, yet she had not weaned her last child, who was 7 months old. The physical symptoms indicated right tubal gestation. Prag of Malmö operated with the assistance of Gröné. The peritoneal cavity contained over a pint of recent blood and clot, and the bleeding was seen to issue from a sharply-defined raw surface as big as a shilling, on the pelvic peritoneum just below the brim of the pelvis; it was bounded anteriorly and on its median aspect by the right round ligament, and posteriorly and to the right by the caecum. This raw tissue was excised, together with a narrow tract of the surrounding peritoneum, and the serous membrane closed by suture. The haemorrhage ceased at once and for good. Two small, red bodies were found lying loose in Douglas's pouch. The left Fallopian tube and ovary were to all appearances absolutely healthy, and so were the right appendages, but it was thought safer to remove the latter. The patient made a speedy recovery. The parts removed were carefully examined in the Pathological Institute, Lund, Sweden, and Gröné publishes macroscopic drawings and photomicrographs. The raw surface in the peritoneum was made up of tissue, including villi, syncytium, and other elements peculiar to the fetal membranes, implanted on the serous membrane, just as such tissue is found implanted on the tubal mucosa when the Fallopian tube is the seat of pregnancy. The two bodies in Douglas's pouch were without doubt products of conception. The right tube was cut up into sections, none of which showed, under the microscope, the slightest trace of recent relations with an ovum. No trace of a fetus could be detected, as is the rule when an ectopic gestation is interrupted in its earlier stages. Gröné, who has reported the case with great care, seems justified in maintaining that it was a genuine primary abdominal pregnancy. If so, it seems clear that at the beginning this condition may not present any very formidable difficulties; it is remarkable how easily Prag succeeded in what is the first aim of the operator, the stopping of haemorrhage.

PETER OF SPAIN, THE OCULIST POPE.

The thirteenth century has been described as the greatest of centuries, partly because the foundation of some of the chief universities, including Paris, Pologna, Oxford, and Cambridge, may be assigned to it. It witnessed also a remarkable development of architecture, and to it we owe some of the most famous castles and municipal buildings, and the beginnings of many of the finest cathedrals of Europe. This epoch saw the rise of a great national literature in nearly every country in Europe: the Cid of Spain, the Arthur legends in England, the Niebelungen and the Meister-singers and Minnesingers in Germany, the Romance of the Rose and the Troubadours in France, and Dante in Italy. It is no surprise, therefore, to find the first origin of ophthalmology in this century. Bernard Gordon, the Scotsman, teaching medicine at Montpellier, had advised the use of spectacles for presbyopia, and in the same century Pope John XXI, Peter of Spain, produced a little volume on diseases of the eye. In the current number of *Ophthalmology*, Dr. Walsh gives a short account of this book, which is of great interest to students of medical history. It possesses great literary value, because it is one of the earliest books written in the Italian language, and is frequently referred to in the dictionary composed by the Accademia della Crusca. It commences with the usual invocation, "*In nomine Dei Amen.*" Then we are given an account of the anatomy of the eye, which is said to be composed of seven tunics and three humours. The humours are the albugineous (aqueous), the crystalline, and the vitreous. The first tunic is the retina, and Peter seems to have had some vague notions of its importance in vision. The choroid he calls the secundine tunic, and then he mentions the scleros (*sic*). The fourth tunic is the *tela aranea* (the spider's web), by which it is believed the iris was intended. The fifth tunic he calls the uvea, and the last two have their present names, the cornea and the conjunctiva. Peter recognizes eight ocular muscles, the four recti he calls *lacerti*—that is, reins. He had a good knowledge of many diseases. Squint he attributed to an affection of the eye muscles, but this, he said, was due to a defect in the brain, thus anticipating Worth's theory of the congenital absence of the fusion centre. Pterygium is described as ungula, from its fancied resemblance to a nail; it was to be cured by an application of eel's blood. Blepharitis was to be treated by epilation. Lacrymal fistula is said to be very difficult to cure, so difficult, indeed, that it must be excoriated. Peter describes cataract, calling it "water which descends into the eye." This is but a translation of the Arabic term for the disease, *al ma an-nazil fil ain*. The modern *fellaheen* in Palestine call it "*moje zerka*," or blue water. He does not mention couching, but this operation may have been described on some of the lost pages of the manuscript. The eye, he says, may be affected by two kinds of hardening—*petrositassor petrosezza* or *tenebrosité* seems to refer to orbital phlegmon, while *dureté* may be glaucoma. For further details of this most interesting book the reader is referred to Walsh's very readable article.

THE CONDUCT OF COURTS.

HUMAN brains being as they are, it is almost inevitable that on most subjects there should be more or less marked difference of opinion; hence it is natural that all judges should not be of one mind as to what kind of conduct on the part of the president of a court is best conducive to the ends of justice and to the preservation of his personal dignity. Equally natural is it that those who are not judges should form some-

what varied opinions on the same points. Thus some rather despica judges whose fashion it is to treat witnesses appearing before them with unvarying courtesy, to receive their statements, however remarkable, without open betrayal of disbelief, and carefully to refrain from expressing opinions based neither on the evidence before them nor on any real knowledge of the subject of their discourse. Others, on the contrary, admire such judges, and regard those who browbeat willing witnesses, and constantly air their own views, as persons mistakenly placed in a position which is always one of authority, and should also be one of immovable dignity. Clearly, if one of these views is right, the other must be wrong; but to the non-legal mind it is not altogether easy to decide between them. Doubtless, on theoretical grounds, a good case could be made out in favour of the one method or the other, but no practical weight would attach to any decision not based on a careful comparison of the net results in an equal and sufficiently large number of cases. Such a comparison is at present quite impossible, because ever since the disappearance of judges of the type of Judge Jeffreys or Lord Braxfield the vast majority of cases have been tried by persistent adherents to the first-named method, which may be described as *suaviter in modo, fortiter in re*. Nevertheless, the difficulties in the way of a really scientific and satisfactory solution of the problem are not insuperable. In the course of time an industrious searcher might amass, say, 100 complete records of cases tried on the other or witness-bullying and inane-observation principle, and thus secure the lacking factor for a comparison of the kind desired. It would be a laborious task, but the researcher might get a useful hint as to promising prospecting grounds from those already well acquainted with the methods of different judges. The newspapers likewise occasionally furnish what seem like useful clues on the subject, as, for instance, in the case of one particular trial at the last Dorchester Assizes. If correctly reported, this was an admitted case of attempted suicide, and the prisoner's friends, deeming him a sufferer from melancholia, seem to have instructed counsel to endeavour to secure for him treatment conducive to his recovery. To this end a medical man who had treated the patient for some weeks after his attempt to cut his throat was put into the witness box, and in answer to a question on the subject gave a clearly worded and appropriate reply. It does not, however, seem to have pleased the presiding judge, for his lordship at once broke in with a flat contradiction; the statement was nonsense, and he himself knew much better. On the witness replying that he had only given his opinion, the judge said he did not care for his opinion, and ordered him out of the box. Practically the opinion expressed by this witness was to the effect that the recovery of a patient suffering from melancholia would best be ensured by his treatment in a civil asylum, prison environment in the circumstances being undesirable. This would seem in itself a sound view to take; but of course, after the dictum of this learned judge, we must believe that it is not so. As it is never pleasant to a man to have his statements aspersed as nonsense by a person to whom he cannot safely reply, it seems possible that this medical witness may have been rather annoyed by the incident. All medical men, however, are more or less philosophers, so it is to be hoped that he consoled himself by the reflection that this judge must be one of those who deem elevation to the Bench a diploma of omniscience, and ordinary courtesy as inconsistent with the due administration of justice.

DEATH CERTIFICATION AND CORONERS' JURIES.

A BILL, at present awaiting consideration by Parliament, proposes to relieve coroners' juries of the duty of viewing a body before proceeding to their inquiry; but Mr. F. W. Lowndes, surgeon to the Liverpool Police, who has had a wide experience in medical jurisprudence, seems disposed to believe that the best thing to do with coroners' juries would be to abolish them altogether. The suggestion is notable, and to some minds may seem anarchical, since the coroner's quest is an institution of such hoary antiquity that it now appears to be an essential part of the British constitution. Coroners' juries, indeed, have had their share in the administration of justice for so many centuries that their origin is not easy to trace. Possibly they date back to the days when the High Court of Justice, from the inquest room to the Court of Appeal, was entirely represented by a word and skin clad village headman and his elders; still, in spite of its novelty, the suggestion is one for which, at first sight, at any rate, there would seem much to be said. It is, for instance, by no means clear that the finding of a coroner's jury is an essential wheel in the machinery of justice. There are many British colonies whose legal procedures are based more or less on those of England, but which nevertheless get on perfectly well without coroners' juries; and north of the Tweed no summons to act as a jurymen at an inquest has ever been issued. Even in England the part played by a coroner's jury would seem much more prominent than important. In the majority of inquests there is no room for real doubt as to the responsibility for the death of any persons connected with it. There are other cases, of course, in which criminal issues are involved, and there may be room for doubt as to the category in which the crime should be placed, and as to whether the name of any particular individual should be specifically coupled with the verdict; but even in these the points raised would seem at least as likely to be properly decided by one intelligent and experienced man as by twelve men of no particular education and no special experience whatever. Furthermore, the fact that coroners' inquiries and magisterial trials may often be seen proceeding side by side would seem to indicate that even now the part played by coroners' jurymen is in a measure superfluous. The police, indeed, are in no wise bound by any conclusions a coroner's jury may reach, and it would be possible to secure the trial and conviction of a man for murder or manslaughter in a case in which a coroner's jury had failed to return a verdict of any kind. There is room, of course, for two opinions as to the value of the work done by coroners' juries, but it seems clear that a good case might be made out for relieving citizens of the duty of taking part in inquiries of this order. The whole subject is in a measure bound up with that of death certification, the main theme of Mr. Lowndes's paper. On that there is no room for difference of opinion. As we pointed out a few weeks ago, more than fifteen years have passed since a special committee of the House of Commons made a series of recommendations on the subject. They have been generally accepted as perfectly sound, and it is lamentable that there should be such delay in giving any effect to them.

MEAT WINES.

WE have received from Mr. D. Innes Smith, Managing Director of Bendle, Ltd., a letter protesting against the application of the term "meat extract" to the meat substance contained in the "Meat-Port Nutrient" sold by the company. Mr. Innes Smith in his letter

refers to the material in the wine not only as "meat substance" but also as "the digestive products of meat or proteins," and states that all authorities admit that such products are available for immediate nutrition. We are very glad to allow Mr. Innes Smith to make the correction, but we may point out that in the article it was distinctly stated that it was not possible, without a complex analysis of a very large quantity, to determine positively by analytical methods whether meat extract only, or some other meat preparation, was contained in the wines. But in calculating the amount of the substance derived from meat in the wines examined from the amount of nitrogen found, it was, for the purpose of comparison, calculated in each case as meat extract, and this was distinctly stated in the article. If, on the other hand, the nitrogen be calculated into its equivalent as protein the result reached is 1.4 per cent. in Bendle's Meat-Port Nutrient. It might be added that one of the main objects with which the analyses were undertaken was to determine the alcoholic strength of meat wines which are largely advertised. The fact shown by the analyses which is of special interest to the medical profession is that the meat wines examined were found to contain approximately the same quantity of alcohol as is ordinarily found in port wine.

HEART STRAIN AND OVERSTRAIN.

THE Marathon race, and the object lesson which it has afforded as to the limitation of the powers of human muscle, will in all probability demonstrate in time to come the truth of warnings recently uttered as to the possible overstraining of the powers of the human heart. This latter aspect of the question has been already investigated by Dr. Theodore Schott at Naheim, and in a fourth enlarged edition of his pamphlet on the overstrain of the heart he has recorded some further observations carried out by the aid of X-rays and the orthodiagraph. While every one recognizes the fact that over-exertion produces an excessive heart beat and a varying degree of dyspnoea, the exact condition of the heart under such circumstances does not appear to have been very closely studied, if we may judge from the references to the subject in the English textbooks. It is assumed that a certain amount of distension of both ventricles must ensue during great muscular exertion, and that the occurrence of dyspnoea is a measure of the extent to which the latent reserve of heart force is being drawn upon. It is known that dyspnoea is all the more likely to occur if the ventricular wall is weakened from any cause; but it has been shown that a very marked thinning of the ventricular wall may be present without any *post-mortem* evidence of dilatation. Dr. Schott's endeavour is to show that actual acute dilatation takes place under stress whenever the symptoms of excessive palpable heart-beat and marked dyspnoea are present. He rightly accords to Dr. Peacock the distinction of having first pointed out the danger of heart strain, but he shows that much more attention has been paid to the influence of infective disease as a cause of myocarditis and endocarditis and subsequent dilatation, than to the more immediate influence of overstrain from excessive exertion. Experiments carried out upon healthy subjects after vigorous wrestling, with and without the support of a waistbelt, are carefully recorded, and many cases are quoted in detail to prove the occurrence of acute dilatation of the heart under different conditions, and especially in cases where some previous cause of heart weakness has been present, although unsuspected by the patient

or his friends. The dangers of excessive dancing while wearing tight stays are emphasized and illustrated by some striking cases. The use of *x* rays and the orthodiagraph would seem to have fully confirmed the accuracy of previous observations by percussion alone, but it is clear that orthodiagraphic demonstrations are attended with so many sources of fallacy that too much reliance must not be placed upon them.

SUMMER COURSE OF OPHTHALMOLOGY AT OXFORD.

THE sixth annual course in the department of ophthalmology of the University of Oxford will begin on Monday, July 5th, and terminate on Friday, July 16th. The main idea of the course is to demonstrate on actual patients, as far as possible, the whole range of ophthalmology, in order to make the reading of a textbook more profitable than can be the case when reliance has to be placed on pictures alone. The first part of the course will be concerned mainly with the practical examination of eye patients, the use of the ophthalmoscope, and the estimation of refraction. During the second part the work will be more specialized, and the lectures will be delivered by various ophthalmic surgeons. As on previous occasions, the last two days will be devoted to addresses, special demonstrations, and the examination of interesting and unusual cases. The fee for the course is five guineas. Further particulars can be obtained from Mr. Robert Doyné, M.A., F.R.C.S., Margaret Ogilvie Reader in Ophthalmology in the University of Oxford, 30, Cavendish Square, London, W.

DISTRIBUTION OF DIPHTHERIA ANTITOXIN IN NEW YORK.

THE New York State Health Department is about to begin the distribution of diphtheria antitoxin in syringes, as provided for by the legislature last year. The syringe to be used has been especially devised for the purpose, and as this form of distribution is expensive, on account of the cost of the outfit, and as it is quite possible to prepare a syringe once used for use a second time, the distribution of these syringes will be made on the express understanding that medical practitioners receiving the package of antitoxin containing the syringe shall return the outfit immediately after the employment of the antitoxin to the State Hygienic Laboratory. The postage for such return will be provided. The directions for the use of antitoxin have been carefully revised, and these, with blanks for making reports of results, to be filled out and returned to the department on the termination of the case, will be sent out with each package.

DEATH OF PROFESSOR GAMGEE.

WE regret to announce that Dr. Arthur Gamgee, Emeritus Professor of Physiology in the University of Manchester, died in Paris on Monday morning last, at the age of 67. He had travelled over to Paris on March 22nd, intending to pass two or three days with his old friend Professor Kronecker, of Berne, and to return to England with him on March 26th. It seems clear that Professor Gamgee had already contracted influenza before leaving London, for on taking his temperature in the train to Newhaven, he found that it was 103; nevertheless he went on by the night boat, but grew progressively worse; the immediate cause of death was congestion of the lungs.

DR. S. SQUIRE SPRIGGE has been offered and has accepted the editorship of the *Lancet*. Dr. Sprigge, who has held for a good many years a responsible position on the staff of our contemporary, is the author of the well known and very interesting *Life and Times of Thomas Wakley*.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Anaesthetics.—On Thursday in last week Dr. Cooper introduced a bill to regulate the administration of anaesthetics. It proposes that on and after January 1st, 1911, no person shall be registered by the General Medical Council unless he submits satisfactory evidence that he has received instruction in the administration of anaesthetics, and that after that date any person not a registered general practitioner who shall administer to any person any drug or gas vapour, etc., with the object of producing unconsciousness during any operation, examination, or procedure or childbirth, shall be liable on conviction to a penalty of £10, and on second conviction £20, provided that no person would be liable if acting under the immediate personal supervision of a registered medical practitioner, or believed delay would endanger life. Power is given to the General Medical Council to make the necessary regulations; and the bill would further enact that a registered medical practitioner shall not give a certificate of death in the case of any person who has died during the administration of an anaesthetic, under a penalty of £5. There is a proviso to the effect that nothing in the Act shall prohibit a person registered under the Dentists Act before the commencement of this Act from administering an anaesthetic during a dental operation or procedure. The bill is backed by Sir Walter Foster, Sir William Collins, Dr. Rutherford, Sir John Benn, Mr. Acland Allen, Mr. Barnes, Mr. Bertram Straus, and Mr. H. Carr-Gomm. It is most probable that the bill, if read a second time, will be referred to a Select Committee to inquire into the whole subject.

Vivisection.—There are four Bills before the Commons dealing with experiments on animals. One, the Dogs Protection Bill of Sir F. Banbury, exempts dogs from all experiments under penalties; a second, called the Cruelty to Animals Bill (No. 2), has been introduced by Mr. George Greenwood and ten other members, to restrict and regulate all experiments on animals, to provide for licensing persons to experiment under very strict conditions, and to increase powers of inspection. Two other bills, standing in the names of Sir George Kekewich and Mr. Hodge, called respectively Prohibition of Vivisection and Vivisection (Abolition) Bills, aim at the suppression of experiments on live animals altogether. None of these bills have a good place, but they require to be watched, as attempts may be made to get one of them read a second time late at night if occasion offers.

Nurses' Registration Bills.—There are two bills before the Commons dealing with the Registration of Nurses, the one promoted by Mr. Munro Ferguson and a number of other members, and the second introduced by Mr. Findlay, Mr. Claude Hay, and others. As business stands, neither of these bills has much chance of passing unless the Government decides to give facilities to one of them. The Prime Minister is to be asked to do this by the promoters of Mr. Munro Ferguson's bill, and he is to be asked to receive a deputation to urge the claims of the subject to legislation at an early date.

Small-Pox at Bristol.—Mr. Cave asked the President of the Local Government Board last week whether an outbreak of small-pox had occurred at Bristol; whether, in spite of the advice of the Board's inspector, the board of guardians refused to make special arrangements for the vaccination of unvaccinated children and for revaccination; whether, on the Local Government Board themselves instructing the vaccination officer to provide special facilities, the health committee refused to permit the issue by their medical officer of bills notifying the names of the vaccinators and the places where they would attend for vaccinations; how many cases of small-pox had already occurred in the city, and how many had proved fatal; and what steps the Local Government Board proposed to take in the matter. Mr. Burns said that the answer as regards the first two points in the question was in the affirmative. He understood from a newspaper report of the meeting of the Health

Committee on March 16th that the Committee resolved that no further bills should be issued by the medical officer of health, but that if necessity arose the Committee should be called together. Bills to the effect stated in the third part of the question had already been issued by the medical officer of health. Up to the morning of March 20th 31 cases of small-pox had occurred in Bristol and its vicinity. Three deaths were known to have occurred up to March 17th. He had caused one of the medical inspectors of the Local Government Board to pay two visits to Bristol and the neighbourhood owing to the outbreak, and he had conferred with the authorities and officers concerned as to the precautions which should be adopted, and various measures had been taken accordingly.

Vaccination.—On Tuesday Mr. Robertson put several questions, in the absence of Mr. Lupton, with reference to vaccination. The first referred to the death of a child named Lomas at Hanley, who was vaccinated in January by Dr. Clare, the public vaccinator; about a week after a rash appeared, and an abscess formed under the arm. The abscess was lanced, and the child suffered a great deal and died in February. It was asked whether the President of the Local Government Board would stop the issue of vaccine matter until he had a supply that would not produce such disastrous results. Mr. Burns said that his attention had not been called to this case prior to the question. He had made inquiry about it, and was informed by the public vaccinator that in his opinion the abscess was not due to vaccination, that Dr. Phillips and Dr. Browne, his assistant, who attended the case, were of the same opinion, and that he believed Dr. Read was so too, but he was absent from home. The public vaccinator added that eleven other children vaccinated by him from the same lymph did well. He saw no reason to interfere with the issue of lymph by the Local Government Board. In a subsequent question Mr. Robertson called attention to an alleged death from vaccination at Enniscorthy. Mr. Cherry replied that in December last year the Guardians of Enniscorthy Union requested the Local Government Board to hold an inquiry with a view to ascertaining whether the death of Ellen Cullen was due to vaccination. The board communicated with the doctor who had performed the vaccination in September last, and were informed by him that shortly after vaccination the child got chicken-pox, which was at that time prevalent in the neighbourhood; that when nearly well she suffered from a very severe attack of eczema; that the combined trouble and resulting exhaustion proved fatal to her; that she had been vaccinated with lymph obtained from the board's vaccine department, and that the vaccination was normal and had nothing to do with the subsequent complaints. The board had forwarded a copy of the doctor's explanation to the guardians, who took no exception to the opinion he expressed. He saw no reason for holding an inquiry. With reference to the lymph used in Ireland, Mr. Cherry said that the Local Government Board informed him that the glycerinated calf lymph procured by them under contract from the National Calf Vaccine Institute, Sandymount, Dublin, was, before issue from the board's vaccine department, tested as to its efficiency and subjected to careful bacteriological examination. Its purity was thus insured. The dispensary medical officers throughout the country being aware of these arrangements to secure proper lymph, a further certificate of the purity appeared to the board to be unnecessary.

Tuberculous Cows.—Mr. Tyson Wilson called the attention of the President of the Local Government Board to a case in which cows condemned for tuberculosis of the udder had been sold, and asked him to inquire whether the cows had been killed and the meat sold to the public, or whether they were still being used for dairy purposes. Mr. Burns answered that he had made inquiry on this subject. He understood that on January 26th last the veterinary inspector of the London County Council certified three cows on this farm to be suffering from tuberculous disease of the udder, and that Mr. Goulding undertook not to use the milk from these cows. He also understood that the cows were afterwards sold, and that they eventually found their way to Salisbury Market, where they were

again sold, and that from that time they were lost sight of. He had not been able to obtain any further information with regard to them.

Sanitary Sleeping Quarters for Seamen.—Last week Mr. Lewis Haslam called attention to the report of Dr. Howard Jones, of Newport, relating to the insanitary condition of the seamen's accommodation in many ships, and asked the President of the Board of Trade to take steps to improve the conditions. Mr. Churchill replied that on the receipt of the report in October last the Board of Trade at once made inquiries into the particular case referred to by the medical officer, and the defects which had been observed were made good. Similar action was always taken when particular cases were reported by the local sanitary authorities. The Merchant Shipping Acts gave full power to secure that crew spaces on British ships should be in all respects available for the proper accommodation of the men who occupied them. These provisions did not apply to foreign ships.

The Factory Surgeon at Horwich.—On Monday Mr. Tyson Wilson asked the Secretary of State for the Home Department whether he had received a petition against the appointment of Dr. Rigby, of Adlington, as factory surgeon for the Horwich district; whether he was aware that the gentleman appointed lived a considerable distance from the district in which his duties were, that there were six medical men resident in Horwich who were all fully competent and qualified to perform the duties, and that inconvenience had been caused by the appointment; and whether he would reconsider it, with the view of appointing a resident medical man to the position. Mr. Secretary Gladstone replied that he had received two letters from the urban district council of Horwich on the subject. The facts were: Horwich and Adlington were contiguous districts, and, prior to the appointment referred to, had each a certifying surgeon. As, however, there were few factories in the two districts—thirty in Horwich and seventeen in Adlington—and the area was small, it was decided, in accordance with the usual policy of the department, on the recent retirement of the Horwich surgeon, to amalgamate the districts; and the appointment for the combined district was given to Dr. Rigby, who was already surgeon of Adlington. Dr. Rigby lived only a short distance from Horwich (about two miles), and visited Horwich (where he had a room) at least twice a week, and oftener if necessary. He had not been able to hear of any inconvenience caused to employers by the arrangement; but the district council stated that complaints had been made of inconvenience caused to children in cases where they had to attend at the surgeon's room, and he had asked the council for further particulars.

West Bromwich Medical Referee.—Mr. Wardle asked the Secretary of State for the Home Department whether he was aware that Dr. Langley Browne, of West Bromwich, who was the medical referee under the Workmen's Compensation Act, was also a director of the Birmingham and Midland Assurance Company; and whether he would say what action he proposed to take with a view to avoiding prejudice in cases in which Dr. Langley Browne was called upon to give an opinion. The Under Secretary for the Home Department reported that the Secretary of State had not previously had this matter brought to his notice. Dr. Langley Browne, who was a practitioner of considerable standing, was a medical referee under the Act of 1897, and was reappointed under the Act of 1906. The matter would have the Secretary of State's consideration, and he would let the hon. member know the result.

Pleas of Insanity, Scotland.—Last week Mr. Watt referred to the number of serious cases in Scotland in which pleas of insanity were being accepted, and asked whether in view of the fact that such pleas depend on expert evidence, the Lord Advocate would take steps to see that the poor man suffered no disadvantage. Mr. Ure replied that his attention had not been called to the number of these cases. Where a plea of insanity was tendered, he was not aware that a poor man suffered any disadvantage as compared with a man who could afford to pay for expert evidence.

MANCHESTER AND DISTRICT.

EFFECTS OF THE POOR LAW COMMISSION.

It will be interesting to see how the Chorlton Board of Guardians will receive a motion, of which notice has been given by a member of the board, to the effect that any person requiring medical relief in the union should be able to choose his own doctor and that the board should pay for such relief on a scale to be fixed. This has, no doubt, been suggested by the recommendation in the Majority Report of the Poor Law Commission, though the motion goes beyond what the commissioners actually suggest. The proposal of the report is not that paupers who have made no self-provision against sickness should be able to choose their own doctor, but that strong inducements should be offered to get all the working classes with an income below a fixed wage limit to join some provident dispensary, and only then when they have become members of a dispensary shall they have a choice of the doctors on the dispensary staff. The commissioners express a hope that in course of time it will be possible to do without the district medical officers, but evidently that is looking forward to a time when all, or nearly all, the working classes will have been induced to join some provident society, and in the meantime, until that is accomplished, the district medical officers would have to be retained as at present. Choice of doctors for those persons who make no self-provision is not suggested by the commissioners. There may be a good deal to be said for the motion which is to come before the Chorlton Guardians, but it should be perfectly understood that it is much out-bidding the Majority Report, and it would be a pity if the majority scheme should be prejudiced by an impression that it proposes such a radical change as the Chorlton Board is asked to consider.

POOR LAW MEDICAL OFFICER AND PUBLIC VACCINATOR.

At the fortnightly meeting of the same board the resignation of Dr. Mumford as district medical officer for Chorlton-cum-Hardy was accepted, and it was also decided to terminate his contract as public vaccinator for the district. It was stated that the salary paid to Dr. Mumford had been £30 a year, and that for this he had had to do a great amount of work. The position of public vaccinator which had been held in conjunction was supposed to compensate in some measure for the small salary, but last year the vaccination fees only amounted to £31. The clerk of the board said he thought a salary of £30 was totally inadequate. It may be noted that Mr. Francis Chandler, one of the Poor Law Commissioners who signed the Minority Report, is an ex-chairman of the Chorlton Board of Guardians, and in signing the report he subscribed to the following sentence: "The conditions under which district medical officers carry out their duties is as unsatisfactory as their remuneration is demoralizing." Possibly the guardians took to heart this and other similar remarks of both the Majority and the Minority Reports, for in a fit of magnanimity they resolved to advertise for a district medical officer for Chorlton-cum-Hardy at the increased salary of £40 per annum.

THE MANCHESTER PORT SANITARY AUTHORITY.

A memorial has just been presented to the Manchester Port Sanitary Authority by about a score of leading shipping firms in Manchester, complaining that the methods of food inspection adopted by the authority are having the effect of hampering the trade of the port. While the memorialists approve of the principle that only sound food should be allowed to enter the port, they submit that until the inspection at other ports is made as strict as it is at Manchester, the interests of the traders of the port will be damaged. They therefore ask the authority to use its influence with the Local Government Board to have pressure brought at other ports in order that the methods of inspection may be made uniform. Dr. Dearden, the port medical officer, said that, besides Manchester, London was the only other port where the rules for inspection were properly carried out. Hull and Newcastle have also begun to put in force the regulations, but other ports show a considerable amount of laxity. As showing the necessity for

strong action, it may be noted that during the past month nearly 3 tons of oranges and 5 tons of onions have been seized, and altogether 11 tons 4 cwt. of food were condemned in addition to voluntary surrenders. For some time the Liverpool Port Sanitary Authority refused to meet the Manchester authority to consider the subject, but it is now announced that a conference has been arranged. The memorial is to be sent to the Local Government Board, which is already considering how to secure a general uniformity, and it is hoped that other ports will be brought up to the standard set by Manchester and London.

CAMBRIDGE.

MEDICAL INSPECTION AND THE TEETH OF SCHOOL CHILDREN.

THE municipality of Cambridge is in some respects one of the most progressive in the kingdom in regard to public health. Some years ago the Cambridge Town Council appointed a medical inspector of school children, and the members were actually surcharged by the Local Government Board's auditor for doing what the Education (Administrative Provisions) Act, 1907, so soon after made compulsory. This surcharge was afterwards remitted by the Board, which however pointed out that the council's action had been illegal. Following on this, the council took advantage of the new Act to appoint in 1907 a dental inspector at a salary of £50 a year, and through the generosity of Mr. Sedley Taylor this work of dental inspection was supplemented by dental treatment, and so the first dental clinic in connexion with elementary schools in this country was established. The report of the work thus done during the year ending October 28th last has recently been published, and the results are so satisfactory that the town council unanimously decided to continue the work at the expense of the rates. The estimated cost is about £410 a year, which represents 1d. in the £. No one nowadays will question the fact that this is a wise outlay of public money, and one which will bring a large return in the way of increased health and efficiency in the rising generation. The experiment is one that is certain to be closely watched by other authorities throughout the kingdom. Cambridge is to be congratulated on the generosity and enlightenment of Mr. Sedley Taylor, who made the experiment possible, and the members of the Town Council on having so heartily taken it up.

RESULTS OF THE SEWERAGE SCHEME.

Another proof of the town's progressive spirit is furnished by a paper on "Cambridge To-day: its Health, Life, and Social Conditions," by Alderman Dr. Dalton, Chairman of the Public Health Committee. Dr. Dalton is able to show that the result of the sewerage scheme carried out in 1895 has been a material lowering of the level of the subsoil water and a remarkable concurrent improvement in the health of the district. Thus, in the period from 1891 to 1905, while the general death-rate of England and Wales has decreased by 9 per cent., that of Cambridge has decreased by 14.66 per cent.; the phthisis death-rate has declined by 20.3 per cent., as compared with 15.3 per cent. in England and Wales generally; while the cancer death-rate has declined by 22.3 per cent., although it has actually increased by 14.9 per cent. in the rest of the country during the same period. These figures are very encouraging, and are quite conclusive of the wisdom of the very costly scheme which was carried out in 1895.

ADDENBROOKE'S HOSPITAL.

The committee of Addenbrooke's Hospital found itself last September under the necessity of making another special appeal for increased annual subscriptions. In response, about £2,000 has been received, but of this amount only £500 represents new or increased subscriptions which will recur this year. The deficit is expected to amount to £1,300 or £1,500, and in order to place the hospital on a sound financial basis the committee consider that the annual subscriptions should be increased by £2,000 a year; at present, excluding a grant of £300 from the university, they amount to £2,344, while the income from investments was in 1907 £1,829, the expenditure was over £10,000, and the difference has been made up partly by means of collections and donations, and partly by

rising legacies for current expenses. Any curtailment in the work of the hospital would be a serious matter, not only for the town and county, but also for the medical school, and it is therefore hoped that non-resident members of the university may show themselves ready to help the hospital by becoming annual subscribers.

BIRMINGHAM.

THE MEASLES EPIDEMIC.

DURING the three months ending February 27th, 2,351 cases of measles have been reported by school teachers, school attendance officers, and health visitors, and it is estimated that there have been altogether nearly 8,000 cases of measles during these three months. The number of deaths during some weeks was very large; as many as 45 have been recorded in one week. Dr. Robertson, M.O.H., considers that the present method of reporting cases is, from the point of view of prevention, probably as satisfactory as compulsory notification. Both forms of notification are insufficient, as they do not let the health department know of the existence of every case in its earliest stage, when effective advice could in a great many instances be given. There is evidence that the incidence of the disease and the liability to attack was not so great in infants' schools which were well ventilated as in those where teachers and scholars were accustomed to a close atmosphere. Some time ago the Education Committee instructed the teachers in four of the large infants' departments to issue notices to the parents of all the children in any class in which a case of measles had occurred. This notice indicated the symptoms to be looked out for, and recommended that the affected child should be kept in a warm room. This scheme worked so smoothly that the Education Committee has recently adopted it generally in all the infants' departments. Dr. Robertson has pointed out in a recent report that the lessening of the mortality from measles is mainly to be expected from the attention given by the health visitors and others to the instruction of parents in the methods of warding off dangerous complications. While it might be possible to delay epidemics to some extent, yet the infection of measles is so extremely diffusible—since one child will infect a larger number of susceptible children than in any of the other infectious diseases—that epidemics must, he thinks, of necessity occur. The mortality of the disease can better be reduced by means of the warning notices than by attempts to delay the epidemics.

WALES.

A MEDICAL BLACK LIST.

THE account given in the *Western Mail* of a letter read at the meeting of the Cardiff Board of Guardians last Saturday, from the Poor Law medical officer for the Penarth and Dinas Powis district, and of certain interviews with local medical men practising in Penarth, throws a curious light on the economic position of the district, which lies on the south side of Cardiff Bay, and is practically a suburb of Cardiff. Dr. T. F. Roche, Poor Law medical officer, in his letter to the board of guardians complained of the considerable increase in the number of poor persons now applying to him for parochial medical attendance; he attributed this to a system adopted by the combined junior medical profession at Penarth of jointly "black listing" their debtors and boycotting them. He alleged that there were 600 to 700 poor families already on the list, and that they could not get a visit from a local doctor without first producing a fee of 3s. 6d., on the understanding that if on the first visit the case proved to be likely to overtax the patient's capabilities of finding ready money, the fee was to be handed back and the case declined. Dr. Roche added that if he also refused, the only course open to them was to apply to the relieving officer or overseer of the poor for a medical relief order. Rather than undertake the obligations

which an official order entailed, and the burden of reporting on all these cases weekly, he had been giving them the attendance they required without the intervention of the relieving officer. From the statements made to our contemporary by local medical men interviewed in Penarth, it is a mistake to say that it was only the junior members of the profession who were concerned in the matter, for all the doctors in Penarth, with one exception, had come to an arrangement about fifteen months ago under which each was supplied with a list of the names of people who had contracted debts and failed to discharge them after a period of over twelve months. This action was not directed against the poor of the town, and all the doctors in Penarth attended poor people, knowing that they could not pay, and not expecting them to pay. The action was really directed against people who could afford to pay for medical attendance—people who drew good salaries and owned the house they lived in. There were about 600 names on the list, the majority being those of people owing money to as many as three or four medical men; a name was only put on the list when twelve months had elapsed from the time of sending the account.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

EDINBURGH SCHOOL BOARD ELECTION.

ON April 2nd the citizens of Edinburgh have to elect twenty-one members to serve on the new board. Dr. James Smith, of Brunton Place, Edinburgh, is one of the candidates. Under Section 4 of the new Education (Scotland) Act power is given to the board to "supply medical officers or nurses, and to provide appliances or other requisites" to carry out the medical examination and supervision of the pupils. It is very desirable, therefore, that there should be one or more members of the medical profession on the new board. Other sections of the community look after their interests in getting representatives elected, but the medical profession is generally rather apathetic. It is hoped, however, it will rally round Dr. Smith.

LOCAL GOVERNMENT BOARD FOR SCOTLAND.

Mr. J. Patten MacDougall, C.B., is about to retire from the Vice-Presidency of the Local Government Board for Scotland, and the position has been offered to Sir George McRae, M.P. for South Edinburgh, who it is stated, has informally intimated his acceptance. The salary is £1,370. Sir George McRae is a member of a firm of balters in Edinburgh, and he was at one time the highly successful treasurer of the city. A few weeks ago it was rumoured that Sir George McRae had been offered an appointment in connexion with the Scottish Prisons Board, at a salary of £1,100, but that statement was officially denied. Sir George McRae's appointment will necessitate a by-election in South Edinburgh, where he had a majority of 4,174 at the last general election.

EDINBURGH ROYAL INFIRMARY RESIDENTS' CLUB.

A meeting of this club was held in the large clinical surgery theatre of the Royal Infirmary on March 23rd. Dr. Alexander James in the chair. The president referred to the death of Professor D. J. Hamilton, who was the president of the club for the current year. Dr. Byrom Bramwell was nominated by the committee and elected by the club as president for the remainder of the term, and he will preside at the annual dinner in June. The constitution of the club was altered. According to the new constitution, each resident physician or surgeon on being appointed by the managers of the infirmary becomes *ipso facto* a member of the club, to the funds of which he is invited to pay an entry fee of 5s. The treasurer, Dr. W. Macrae Taylor, submitted proofs of the new edition of the list of members, and requested all present to notify to him any change of address of any member of which they might be cognizant.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

THE CRIPPLES' INSTITUTE, BELFAST.

The annual meeting of the Incorporated Cripples' Institute, People's Palace, and Bangor Homes of Rest, was held in the Institute, Belfast, on March 24th. The chair was taken by the Lord Mayor. Mr. Norman Barnett presented the surgical report on the institute, and drew attention to the fact that nearly all the cases were due to tubercle; considerable improvement followed the prolonged care rendered possible by the institution which would not have been received at the patients' own homes. Dr. Gorman presented the medical and surgical report of the Homes in Bangor, where 40 children were in residence at the beginning of the year and 80 had been since admitted, many of whom required medical or surgical treatment.

NATIONAL SERVICE LEAGUE.

The importance of the principles of the National Service League, more especially in their influence upon the physical health of town populations, has been fully recognized by the medical profession in Dublin. A branch of the league has been established, consisting of 270 members, of whom 36 are medical men. At the annual meeting held recently the Presidents of the Royal College of Physicians and the Royal College of Surgeons both spoke in favour of the league's principles. The president of the Dublin branch is the Earl of Meath, K.P., and the honorary secretary is Dr. John B. Story, 6, Merrion Square, Dublin, from whom further information can be obtained.

Correspondence.

HUNGER PAIN AND DUODENAL ULCER.

SIR,—Mr. Moynihan's letter obliges me to trouble you again. He takes up the position that because he has performed gastro-jejunostomy for so many cases in which he had diagnosed duodenal ulcer, therefore the duodenal ulcers must have been there. What is the proof of this? All my surgical colleagues tell me that it is not possible to know in many cases whether there is a duodenal ulcer or not. This point ought to be cleared up. Mr. Moynihan tells us he operates with no other ground but the history of the case, and he contends that that is sufficient, and appeals to his operations as proof of the correctness of his diagnosis. I want to challenge the validity of this appeal and to affirm that a surgeon who performs a gastro-jejunostomy for a supposed case of duodenal ulcer is not, in a large proportion of cases, in a position to say whether there is a duodenal ulcer or not.—I am, etc.,

Birmingham, March 29th.

ROBERT SAUNDREY.

P.S.—It has been pointed out to me that six hours, the interval of time after the test meals given in my letter last week, is shorter than in my previously published writings. Up till a short time ago I allowed eight hours, and it would be better for experimenters to stick to this for the present, as it is with that period that I can claim a lengthened experience, but I have lately used six hours, and have not, so far, been misled by it. It is clear that the shorter the interval the stronger the evidence of the absence of obstruction.

SIR,—I have read with the greatest interest Mr. Moynihan's letter in the JOURNAL of March 27th. I think it right to add the evidence obtained in my more limited experience to that given by him. During the past eighteen months I have operated on 50 cases of duodenal ulcer (perforative or non-perforative) in which the diagnosis of the locality of the ulcer, based mainly on the presence of this symptom, either by myself or by the physician who submitted the case to me for operation, was absolutely confirmed at the time of operation. As stated by Mr. Moynihan, there was not the slightest difficulty in recognizing and demonstrating the presence of an ulcer or its results. The condition which in my experience is most likely to simulate this symptom is one of

cholelithiasis, in which the gall stones are limited to the gall bladder, and are small, multiple, and smooth.

In such cases I have found that the contractions of the gall bladder associated with the demand for a supply of bile when the food enters the duodenum, may give rise to a type of pain very like the so-called hunger pain. It is, however, neither so persistent nor so regular in its recurrence after each meal, and is very frequently associated with nausea or vomiting, which are generally absent in duodenal ulcer.

The suggestion that the cases under consideration should be submitted to a surgeon for "exploratory operation" is repugnant to every operating surgeon. The operation is not for diagnostic purposes but for the treatment of a pathological condition which can be recognized with great accuracy by the expert physician.—I am, etc.,

Belfast, March 27th.

A. B. MITCHELL, F.R.C.S. Ire.

SIR,—After reading the recent correspondence on the diagnostic value of "hunger pain," I find it difficult to accept Dr. Hutchison's theories in face of Mr. Moynihan's operative experience in over 230 cases of duodenal ulcer. Mr. Moynihan states that his operations reveal that he is mistaken in less than 5 per cent. of the cases, in which he has diagnosed a duodenal ulcer on account of the occurrence of the symptoms, including hunger pain, which are generally regarded as due to a functional condition called "acid dyspepsia" or "hyperchlorhydria." He appears therefore to have proved that this disease, which has been diagnosed for years as acid dyspepsia or hyperchlorhydria, is really duodenal ulcer. But every hospital physician who sees out-patients, and every general practitioner knows how common this condition is. He also knows how amenable it is to treatment, how the symptoms can be instantaneously relieved and in time be caused to disappear completely.

Between 1826 and 1892 *post-mortem* examinations were made on 17,652 cases at Guy's Hospital; in 62 of these an unhealed duodenal ulcer was discovered, but in only 20 was it the direct cause of death by perforation, haemorrhage, or stenosis of the bowel or common bile duct. The presence of an ulcer can be recognized with more certainty by a thorough examination of the inside of the duodenum after death than by examination of its outside at an operation, so that our records of the pathology of the dead are probably even more reliable than Mr. Moynihan's observations on the "pathology of the living."

We can thus draw the following conclusions from clinical experience, *post-mortem* records, and the observations of Mr. Moynihan, the Mayos and other surgeons: (1) Duodenal ulcer is an exceedingly common condition; (2) it is easily cured by medical treatment and is fatal in an extremely small proportion of cases, as in less than ten years Mr. Moynihan has proved the existence by operation of nearly four times as many cases of duodenal ulcer as were found unhealed in 17,652 consecutive autopsies, and more than eleven times the number which proved fatal in sixty-six years at one of the largest hospitals in the kingdom.

It is thus obvious that the proper treatment of duodenal ulcer is medical and not surgical. Mr. Moynihan should rest content with having taught us a most valuable lesson in the symptomatology and prognosis of duodenal ulcer, and should cease to perform what his own work has clearly demonstrated to be an unjustifiable operation in the vast majority of cases. If, however, he decides to continue his researches on "the pathology of the living," I should be most grateful to him if he would give me an opportunity, such as he has offered to Dr. Hutchison, of personally observing some of his cases, and of seeing on what evidence he bases his diagnosis of duodenal ulcer at the operation as well as before it.—I am, etc.,

London, W., March 28th.

ARTHUR F. HERTZ.

THE TREATMENT OF SCHOOL CHILDREN.

SIR,—I should like to add my word of warning to that of Dr. Lyster published in the BRITISH MEDICAL JOURNAL of March 27th, p. 817, as to the urgent need of common action on the question of treatment as a consequence of medical inspection.

It is quite clear that many education authorities are blindly feeling it the obvious way, and the simplest thing in the world, to make an arrangement with the existing

hospitals to render services in return for a subscription. What is, perhaps, more surprising is that hospital managers are tumbling headlong into the same morass. Neither body seems to see that municipalization lies that way. And yet a moment's reflection will make it clear.

If once hospitals accept subsidies from the rates voluntary subscriptions will cease; wealthy people will not pay both ways. When once it is clear that children whose parents can well pay are being sent to the hospital under the "recommendations" of the education authority, the medical staff will resent it. Thus the hospitals are between the devil and the deep sea. No one who knows anything about hospitals will dispute the statement that only a slight turn of the screw is necessary to make every hospital in the kingdom insolvent. At first the evil day will be staved off by larger and larger subsidies, but municipalization is the inevitable end. This may be good or it may be bad, but it ought to be clearly foreseen.—I am, etc.,

Stafford, March 29th.

JOHN PRIESTLEY.

RATIONAL DRESS FOR THE SOLDIER.

SR.—With reference to the leading article in the JOURNAL of March 13th on the "Marching Soldier," may I point out that about ten years ago, in an article on "Rational Dress for the Soldier" published in the *Indian Medical Gazette* of November, 1899, I advocated "a coat that could at all times be worn loose and open."

I had for some years observed that a great amount of suffering, disablement, and disease (especially heat apoplexy) were caused by the dress of the soldier in India, and I advocated that the common-sense style of dress adopted by the civilian workman should be used by the soldier, but I looked in vain for any recognition of my observations, or any approbation of my recommendations from the official world, from which I should have expected them.

The dress was warm and nearly waterproof, buttoned up and strapped down by belts and putties. It gave rise to overheating and exhaustion. My chief recommendations were that no putties should be worn, and no belts over the coat. I also advocated a shirt cooler than the present woollen one. I desired that the dress of the soldier on duty should be assimilated to that worn by officers and civilians when engaged in severe exercise, such as hunting or shooting. The present dress seemed to me unscientific, cruel, and wasteful of the men's energy.

I shall be glad to send my essays to any one interested in this important question. My remarks apply chiefly to hot climates.—I am, etc.,

Kingstown, co. Dublin, March 21st.

C. J. MCCARTIE,
Lieut.-Col. I.M.S.

DISINFECTION BY STEAM.

SR.—In the note on Disinfection by Steam, published in the JOURNAL of March 20th, 1909, p. 741, some references are made to an article which I have recently published on The Essentials of Disinfection and Sterilization by Steam (*Medical Chronicle*, December, 1908).

To shorten statements which I had tried to condense to the utmost, some sentences have necessarily been omitted by the writer of the note, and these omissions alter very considerably the meaning of my text. I would therefore be much obliged to you if you would reproduce verbatim the passage regarding which I think misunderstandings are likely to arise. I do not think that I could discuss here the facts and experiments upon which the conclusions are based; these, however, will be found explained in my paper.—I am, etc.,

SHERIDAN DELÉPINE.

Public Health Laboratory, Manchester, Mar. 22nd.

Practical Disinfection and Sterilization.

From the data given in the preceding paragraphs it is possible to deduce the conditions which have to be fulfilled in order to ensure the disinfection or sterilization of infected articles.

In discussing these points reference will be made to current steam disinfectors only. When confined steam is used, arrangements must be made for the expulsion of air by special means, and time must be allowed for the working of various devices. It would be inconvenient to introduce details of this kind in a general statement.

1. The time necessary to heat and fill the disinfecter with dry

steam at the desired temperature depends on the method of heating and on the size and weight of the disinfecter. On the supposition that the disinfecter and its contents are cold at the beginning and that the weight of the load is about 100 lb., the time required to fill the disinfecting chamber with steam (steam free from air) at 100° C. will vary (according to the machine used) between 20 minutes and 1½ to 2 hours. Disinfectors of usual size would require at least 30 minutes.

2. For the penetration of current saturated steam free from air through 8 to 10 inches of mattress or blanket, 10 to 15 minutes should be allowed; this time may be reduced when current steam under a pressure of 10 to 20 lb. is used, provided always that some space is left between the articles.

3. With current steam at ordinary atmospheric pressure, 5 to 15 minutes' exposure is required to disinfect products containing pathogenic bacteria of a resistance not exceeding that of the spores of the *Facillus anthracis* (the variations in the time are due to variations in the amount and kind of associated material), but if it is desired to secure complete sterilization of products containing resistant spores of earth bacilli, at least 2½ hours' exposure should be allowed, and sometimes more than eight hours would be required.

The time necessary for ordinary disinfection and for complete sterilization respectively would therefore be as follows:

A. Operations with Current Saturated Steam at 100° C.

	Time taken for Disinfection. Sterilization.	
	Minutes.	Minutes.
For heating and filling disinfecter with steam at 100° C. ...	30 to 90	30 to 90
For penetration of bulky articles such as large mattresses ...	10 to 15	10 to 15
For actual disinfection ...	5 to 15	150 to 480

Total time required from the beginning to the end of the operations, the disinfecter being cold at the beginning ... 45 to 120 ... 190 to 585

Therefore the time necessary for ordinary disinfection by current saturated steam at atmospheric pressure would vary from 2 to 2 hours, and for sterilization from 3 hours to over 9 hours.

B. With current steam at 10 lb. pressure (115° C.) the time necessary for ordinary disinfection would be reduced by a few minutes only, but complete sterilization would be effected much more rapidly than with steam at 100° C. The earth bacilli spores would be killed in from 15 minutes to 30 minutes by steam at 115° C., so that the duration of the whole process of sterilization would take from 55 minutes to 145 minutes (or by deducting the preliminary period of heating 25 minutes to 55 minutes).

C. With current steam at 30 lb. pressure (126° C.) the time necessary to obtain complete sterilization would be from 45 minutes to 130 minutes (or by deducting the preliminary heating period 15 minutes to 40 minutes).

BEER AND THE MATERIALS USED IN ITS PRODUCTION.

SR.—Our attention has been called to an article in the BRITISH MEDICAL JOURNAL of March 13th entitled "Beer and the Materials used in its Production." With that portion of the article which has reference to the practice and science of brewing we are not now concerned, but there are several statements touching on the "purity" and wholesomeness of beer, which are, in our opinion, calculated to mislead your readers, and on these we ask your permission to make the following brief observations:

On reference to the brewing returns for the year ended September 30th, 1908, which is a later one than that referred to by your contributor, it will be seen that 34,953,274 bulk barrels of beer were produced during the year in question, in the brewing of which were used 50,960,923 bushels of malt and 4,196,406 cwt. of grain materials (chiefly unmalted barley, maize, and rice) and sugar. Calculating from these numbers, it will be found that 82 per cent. by weight of the total brewing materials used during the year in question consisted of barley malt. In regard to hops, it may be pointed out that the substitutes employed amounted to only 0.007 per cent., which is obviously an utterly insignificant and negligible quantity. The grain materials used other than barley consisted almost entirely of maize and rice prepared with the utmost skill, and generally of a much higher degree of purity than the same cereals in the condition in

¹ It must be borne in mind that in the above table the times given include the time necessary to heat a cold machine, as a rule, the disinfecter is already hot before the articles to be disinfected are put into it. Therefore, in actual practice, the time required for penetration and disinfection is about 15 to 30'. With regard to sterilization, the times given in the above table would, in the great majority of cases, be excessive, the most resistant spores are not often present in articles which have to be disinfected.

which they are used in the kitchen for the preparation of puddings and other dishes. The sugar consisted chiefly of cane sugar, invert sugar (the main constituent of honey), and starch sugar, with a small quantity of caramelized or burnt sugars, used for their special flavouring and colouring properties. These are all absolutely unexceptionable in respect of purity and wholesomeness, and, it may be added, are largely used in the manufacture of confectionery and other food products. With reference to preservatives, we may point out that these are not, and cannot, be used in substitution of any proportion of the hops, but are employed in minute proportions in certain beers for well-defined technical reasons which it is difficult to deal with in a letter such as this, but which we should be pleased to place before your readers in another communication if you will be good enough to afford us that opportunity. In any case they are present in beer in very much smaller quantities than in a large number of "temperance" beverages and other food products which command a large sale, and the wholesomeness of which is never called in question.

Your contributor speaks of the occurrence of arsenic in certain beers some years ago as being the "chief" instance in which deleterious substances have been found widely distributed in beer. As a matter of fact this is, so far as we know, the *only* instance in which anything deleterious has been discovered in beer, and your contributor must surely be aware that the lamentable consequences to which he refers were the result of a serious and unfortunate oversight on the part of a single firm, and that the same consequences might quite well have happened to a number of other industries.

In reference to the statement that all materials used in producing beer ought to be thoroughly examined by persons competent to judge them, we may point out that this is actually done; and we venture to assert that there is no brewing material used in this country at the present moment which has not been carefully examined by some skilled expert, either on behalf of the manufacturer, or of the brewer, or of both. In addition to this, we may point out that the materials used in brewing are subjected to continual supervision by the officers of the Inland Revenue Department and their expert scientific advisers. Brewers are quite as anxious as your contributor appears to be that the beers they brew shall be wholesome and free from any injurious material whatever; and our large experience of the practice, both of the leading and also of a very considerable number of the smaller brewers in this country, justifies us in asserting that no such materials enter into the composition of beer. On those who assert the contrary lies the onus of substantiating their charge.—We are, etc. (for the Institute of Brewing),

ALFRED CHASTON CHAPMAN, F.I.C.,

Analysis and other Analytical Chemists.

E. R. MORITZ, Ph.D., F.I.C.,
Scientific Adviser to the Brewers' Society.

ALFRED GORDON SALAMON, A.R.S.M., F.I.C.,
Past President of the Institute of Brewing.

JULIAN L. BAKER, F.I.C.,
Secretary of the Institute of Brewing.

The Institute of Brewing, Brewers' Hall, E.C., March 23rd.

*—The figures quoted above from the latest official brewing returns, which had not appeared when the article in question was written, show that malt formed a larger percentage of the brewing materials used in the year 1907-8 than in 1906-7. We may point out that there was no reference in the article to the presence or absence of preservatives in "temperance" beverages, which cannot affect the fact of the addition of such substances to beer. It will hardly be maintained that the use of glucose containing a deleterious proportion of arsenic afforded evidence that all materials used in brewing were "thoroughly examined by persons competent to judge them" in 1900; no doubt greater stringency prevails at the present time, and, in insisting on the importance of such examination, negligence was not in any way imputed to those on whose behalf our present correspondents have written.

MEATY WINES.

SIR,—In your article on "Meaty Wines" you draw attention to what in my judgement is becoming a grave social danger. The specious and ingenious advertisement

of alcoholics under the guise of harmless medicaments is introducing drinking habits into numberless households. Hardly a day passes in which I am not asked my opinion of some drugged or otherwise sophisticated wine; and this occurs to an alarming extent in families hitherto practising total abstinence.

The utter absurdity of the claims made on behalf of these nostrums is of course known to every medical man; but to the public at large the "damnable iteration" of their therapeutic merits in every newspaper and on every hoarding is dangerously seductive, and calls for authoritative condemnation on the part of the medical profession. —I am, etc.,

Brookley, S.E., March 23rd.

J. S. BOOTHROYD.

THE COLD BATH TREATMENT OF TYPHOID.

SIR,—Being solely responsible for the Brisbane typhoid statistics referred to by Dr. G. Parker (p. 754), may I be allowed a few remarks on the above subject?

The effect of a single cold bath on the circulatory system is manifest; the pulse becomes small and hard, its rate reduced. We now know that these changes concur with a rise of blood pressure of from 15 to 40 mm. Hg.¹ The effect of a systematic course of cold bathing is hardly less manifest; the progressive softening (loss of vascular tone) and acceleration of the pulse which occurs to some extent in all cases is lessened and deferred. Formerly these circulatory changes were ascribed to progressive febrile degeneration of the cardiac muscle; increased rapidity was regarded as compensatory of diminished force. And a strong *a priori* case was made out against cold bathing in that it threw extra work on the enfeebled organ. This was difficult to answer except by appeal to experience. Now, however, the advocates of Brand's system are in an entirely different position. Recent work (Crile, Romberg, Passler) has shown that "it is the vessels that are paralysed, not the heart that is damaged." Langdon Brown: The increased rapidity of the heart's action is an attempt to maintain the necessary blood pressure in a vascular system which is unduly dilated; and this undue dilatation is checked and deferred by systematic cold bathing.

The view that the progressive circulatory failure of typhoid fever is an index of progressive vasomotor paresis is consistent with—indeed, explains for the first time—many clinical observations in the hydrotherapy of fever. In my monograph² I pointed out that the influence of cold bathing on the temperature is inversely correlated with its influence on the pulse. Early in the fever the temperature is resistant, and prolonged bathing in comparatively cold water is essential in order to obtain a satisfactory reduction; in the later stages the body temperature is readily reduced, and baths of short duration, or comparatively high temperature, are all that is required. The reverse is true as regards the pulse. Early in the fever the cutaneous vaso-constriction and reduction in pulse-rate is marked; in the later stages both these responses to refrigeration are modified.

All these observations are easily explained on the view that an increasing vasomotor paresis is the dominant factor in the circulatory failure; and so, too, is the conclusion—arrived at by all who have had much practical experience of cold bathing in typhoid—that body temperatures which are readily reduced by refrigeration are for the most part of bad prognostic significance.—I am, etc.,

London, S.E., March 23rd.

FRANCIS HARE.

THE United States Treasury Department has recently issued a statement giving all the items of expenditure in connexion with the last illness of President McKinley, under the appropriation of £9,000 for this purpose made by Congress on July 1st, 1902. The payments to the physicians, as the records appear on the Treasury ledgers, follow: Dr. M. D. Mann, £2,000; Dr. H. Mynter, £1,200; Dr. C. McBurney, £1,000; Dr. Roswell Park, £1,000; Dr. C. G. Stockton, £300; Dr. E. G. Janeway, £300; Dr. H. G. Matzinger, £150; Drs. W. W. Johnston, E. W. Lee, and H. R. Gaylord, £100 each; Dr. N. W. Wilson, £50; Dr. G. McR. Hall and Dr. E. C. Mann, £40 each.

Medico-Legal.

HILLIYER V. THE GOVERNORS OF ST. BARTHOLOMEW'S HOSPITAL.

This case, which was heard by Mr. Justice Grantham and a special jury on Friday and Monday last, raised a question as to the liability of the governors of a hospital for negligence.

Mr. J. B. Matthews was for the plaintiff; Mr. McCall, K.C., and Mr. Norman Craig for the defendants.

It appeared that the plaintiff, a medical practitioner, was admitted to St. Bartholomew's Hospital on March 28th, 1907, in order that he might be examined under an anaesthetic. It was alleged in the statement of claim that, for the purpose of the examination, the plaintiff was placed on an operating table in such a position that his arms were allowed to hang over its sides; that his left arm was in contact with a hot-water tin projecting from beneath the table, and the inner part of his right arm was bruised by the operator or some other person pressing against it during the operation; and that the result of these injuries was traumatic neuritis and paralysis of both arms, and he had ever since been unable to exercise his profession as a medical man. It appeared that the examination was undertaken gratuitously, as the result of representations made by the plaintiff that he had come to the end of his resources. The defendants denied the alleged negligence, and pleaded that if they owed any duty to the plaintiff, it was to exercise reasonable care in the selection of the hospital staff, in which duty they had not failed.

After the plaintiff's case had been opened, it was submitted by Mr. McCall, on the part of the defendants, that no action would lie against the defendants being the governors of a charity which was defined by the 22 Geo. III. c. 77. Moreover, it had been held in a very similar case, *Hall v. Lees*, 1904, 2 K.B. 602, that the duties of a nursing association were satisfied by the supply of duly qualified nurses, and this association was not liable for their negligence. In the present case it was not even alleged that the defendants had failed in taking due care to provide a qualified staff.

To this Mr. Matthews replied that he alleged that there was an implied promise on the part of the defendants to provide that the operation should be conducted with due care, and that they would provide fit and proper persons to place and maintain the patient in a safe position on the table, and a breach of those promises or warranties.

Mr. Justice Grantham decided that the evidence had better be heard.

Dr. Risien Russell said that when he saw the plaintiff in April, 1907, after his visit to the hospital he was suffering from paralysis of the left arm and partial paralysis of the right arm. It was caused by neuritis. Witness had not heard that plaintiff suffered from malarial fever in West Africa. He never knew of a case in which a burn caused by a hot-water tin resulted in paralysis.

Sir Isambard Owen gave evidence for the plaintiff.

The plaintiff in his evidence said that he went to West Africa in 1904 as medical officer to a mine, and returned in February, 1905. In June, 1906, he had an attack of sciatica, but he got better, but in September, 1906, the attack recurred, and he was then treated by Dr. Gardner. In March, 1907, he was examined at the hospital. The day after the operation the warden and the house-surgeon told him that his arms had not been supported whilst he was under the anaesthetic, and that they could not account for the burn on the arm, unless it came in contact with a hot bottle or some hot apparatus. The witness admitted that when the sciatica became acute he began to inject morphine, and that he took a certain amount of alcohol when in West Africa.

At the conclusion of the evidence for the plaintiff, counsel for the defendants again submitted there was no case.

Mr. Justice Grantham, in giving judgement, said that it was impossible for him to allow the case to go to the jury. It was involved in doubt as to the facts. When he was 40 years of age the plaintiff went to the West Coast of Africa. When there he took two or three whiskies and sodas a day. That was the worst thing he could have done. It was not much to be wondered at, that on his return he "took it easy." According to the case as it was opened, he was really employed as a locum tenens; but it appeared that he was really employed only a short time. He was then struck down by sciatica. He had a good friend in Dr. Gardner; but he did not tell Dr. Gardner about the morphine, and continued to take alcohol in spite of his advice. The sciatica forced him to go to the hospital. An examination took place. As to the cause of his suffering after the examination his lordship said he did not understand it. It was suggested that it was caused by a hot-water can; but he could not understand what evidence there was on the point. Nor was there anything to account for the alleged pressure on the right arm. He apparently got bad after some weeks; and as to the right arm the predisposition to neuritis made it become worse. It was clear that the plaintiff had suffered very much before going to the hospital. Against whom was the negligence alleged? If there was any negligence it was that of the surgeon; but it was admitted that he could not make the hospital liable as he was not its servant. Now he had been asked to hold the Lord Mayor and Corporation of London liable. It was said that as a matter of policy he should let this case go to the jury, but he thought it would be a fatal policy to the public to allow a case to go to the jury under these circumstances, because, if he did so, everybody

who happened to have a grievance against the hospitals would be bringing an action "on spec," and raising all sorts of questions which would be disastrous to those who controlled these institutions.

His lordship accordingly entered judgement for the defendants, with costs.

THE BARTITSU LIGHT CURE.

WE learn from a report in the *Daily Telegraph* that the creditors and shareholders met under the winding-up order made against the Bartitsu Light Cure Institute (Limited) on March 23rd. The company was registered in March, 1906, to take over and develop the business of the Bartitsu Light Cure and Electro-Therapeutic Institute, carried on by Mr. E. W. Barton Wright. The company carried on business in Bedford Row and Albemarle Street, apparently at a loss throughout. The directors attributed the failure to lack of funds consequent upon a judgement for a large sum being recovered against the company by a former medical assistant at the institute. A receiver had been appointed on behalf of the debenture holder, and he was now in possession of the assets. The liabilities were returned at £3,260, which is expected to rank against assets £435, after payment of the claim on debentures. The deficiency as regards shareholders is £21,794. The liquidation was left in the hands of the Official Receiver.

RELATIONS OF MEDICAL MEN WITH UNREGISTERED DENTISTS.

WE have received a copy of the *Coatbridge Express* for February 17th, 1909, containing an account of an action brought by Bethia C. Dickson against "The Hygienic Institute" of Glasgow and Coatbridge, claiming damages for serious injury alleged to have been caused to her mouth by an operator in the employment of the defenders when extracting her teeth. Mr. Dunn, L.D.S. (Glasgow), gave evidence in support of the pursuer's case, and said the condition present would have to be treated by a surgical operation. Dr. James Monie of Airdrie proved that previous to the extraction the pursuer was in a healthy condition, and he attributed her present weakly state of health to the extraction. The pursuer said she was called on by an agent of the defenders, who told her that for a certain period his firm would give painless extractions free, and she, thinking it a good chance to get her teeth out, gave him her order. She seems to have paid 16s. in all. The operations were repeated on several occasions, but on one that took place in August, 1908, the operator is alleged to have injured the gum and the jawbone. J. L. Dalziel, junior, of 156, Main Street, Coatbridge, said he was in the employment of defenders as an operator. Owing to the difficult nature of the case, Mr. Miley was selected by the head office to operate. He arranged with Dr. Martyn to be present, and, in fact, he was present, and the witness paid him a fee of one guinea. The doctor was present in the next room. Asked why he was not present in the operating room, witness said Dr. Martyn gave no reason, but could easily have been summoned if wanted. Witness was not a dentist, but he operated and administered local anaesthetics; he admitted having administered anaesthetics that were not local, and denied that the doctor was present in order to supervise the administration of anaesthetics. William Miley, the actual operator, said Dr. Martyn was present in an adjoining room, and within call if necessary. Mary Dalziel, daughter of John Dalziel, senior, manager of defenders at Coatbridge, said that Dr. Martyn was there, and she sat with him in the next room during the operation. David Dunbar, operator in the employment of defenders, gave evidence for the defence, but denied having done any extractions for the pursuer in this case. Dr. David Beaton stated that he had examined the pursuer's mouth, and did not see anything to show that there had been anything improper in the extraction of the teeth. The advocate for the defence put in a citation of Dr. Martyn and closed his case. The case was adjourned to March 15th, when the sheriff took the case to avizandum, and on March 15th delivered judgement, as reported in the *Airdrie and Coatbridge Advertiser* of Saturday, March 20th, 1909, to the effect that the defenders were under obligation to supply the ordinary skill and competence of persons practising the dental art, and that they had failed in this obligation, and were liable in damages to the pursuer, and the damages were assessed at £30, with costs.

At the Grimsby County Court on March 9th, a young woman, a draper's assistant, claimed £3 damages against the Hygienic Institute, of Berne House, Beverley Road, Hull, for the careless extraction of two teeth. The plaintiff had arranged to have a number of teeth extracted and replaced by artificial ones for an inclusive charge of £6. The defendant's representative, a Mr. Brown, extracted eleven teeth after injecting some fluid into the gums. Subsequently there was profuse bleeding, and Dr. Jeffs was summoned. He eventually stopped the bleeding by plugging. He stated in his evidence that, in his opinion, the forceps had been too deeply inserted, and had torn the gum. In answer to the legal representative of the defendant, Dr. Jeffs stated that no fault could be found for the way in which nine teeth had been taken out. The bleeding was accounted for by the cavity produced by the extraction of two front teeth. If the teeth were very bad such a cavity might be caused, but, in his opinion, the operation could not be said to have been skillfully performed. It was stated on behalf of the defendant that the man, Brown, had now left his employment. The plaintiff was awarded £3 damages.

The Hygienic Institute is described in *Truth's Cautionary List* (1909) as being one of the businesses carried on by a Jew of Roumanian origin, named Oscar Farkasch, in association with "J. L. Rosensheim and J. J. Sallmeyer," and is said to have a head office in London, and branches at Glasgow, Hull, and Newcastle. In the Grimsby case it was of course proper that the medical man sent for in the emergency should apply suitable treatment to arrest the hæmorrhage, but in the Coatbridge case some explanation appears to be required as to the allegation that a Dr. Martyn, a registered medical practitioner, was present in an adjoining room during one of the operations, and was paid a fee for attendance. Although he took no part in the proceedings, such conduct, if proved, might be held to come under the terms of the resolution passed by the General Medical Council on December 1st, 1899: "Any registered medical practitioner who knowingly and wilfully assists a person who is not registered as a dentist in performing any operation in dental surgery either by administering anaesthetics or otherwise, will be liable on proof of the facts to be dealt with by the General Medical Council as having been guilty of infamous conduct in a professional respect." It seems probable that the words "or otherwise" in the above resolution would include such conduct as that alleged against Dr. Martyn.

ALLEGED MALPRACTICE.

AT Bow Court Court on March 9th an action was heard, in which the wife of a solicitor at Leyton claimed £250 damages for negligence and careless treatment from a Walthamstow medical man. According to the claim, the medical man treated a fractured femur as merely a dislocated patella, with the result that one of the plaintiff's legs was now 2 in. shorter than the other. After evidence, which showed, among other things, that no malpractice had been alleged until the medical man threatened to sue for his fees and that the patient had caused her servant to remove nightly part of the bandages applied, Mr. Arthur Bryan, the counsel for the defence, claimed that the evidence could not be taken as proving either negligence or careless treatment. On the contrary, the treatment, both as regards the patella and the femur, had been shown to be what it should have been. The presiding judge took the same view, and the case ended in judgement for the defendant with costs.

MOTOR CAB DRIVERS.

THE death of the driver of a taximetric motor cab, found insensible at the Bank Station of the Central London Railway, was the subject of an inquiry at the City Coroner's Court on March 22nd. A representative of the cab company concerned gave evidence to the effect that applicants for employment as driver were medically examined with a view to eliminating as far as possible all risk to the public through the sudden death or other incapacity of a driver when on duty. The deceased when engaged had been examined in this fashion. The medical evidence furnished showed great enlargement of the heart and vegetations on some of its valves; an opinion was expressed that the man's heart must have been perceptibly diseased when he entered the service. The jury returned a verdict of death from natural causes.

PARTNERSHIP AGREEMENTS.

BIRMINGHAM.—(1) Partnership agreements prove too often unsatisfactory because the terms are not fully understood at the time they are entered upon, and each side should consult a solicitor. It is, above all things, desirable that there should be equitable terms of release, so that if the bond becomes intolerable it can be broken. Two years' purchase is a good price to pay by an assistant who is succeeding to only a third of a partnership, unless he is also to be paid his salary as assistant during the two years. The question, how long he should wait before obtaining a larger share, is not easily answered, as the senior partner may be a comparatively young man, and be unable to agree to his income being reduced, but, on the other hand, there ought to be a prospect of the total income of the practice being increased under the partnership, and the greater share might be made contingent upon the total income reaching a certain figure. (2) Equal annual holidays for each partner is the only equitable arrangement.

DISTRICT COUNCILS.

W. A. E., a candidate for the rural district council, does not hold any appointment under the Local Government Board. He asks whether the fact of accepting fees under the Notification of Infectious Diseases Act would debar him from accepting nomination for the office.

* * The acceptance of such fees is no disqualification for the office of district councillor.

Medico-Ethical.

The advice given in this column for the assistance of members is based on medico-ethical principles generally recognized by the profession, but must not be taken as representing direct findings of the Central Ethical Committee.

AFTER-ATTENDANCE OF SUBSTITUTE.

Zeno propounds the following query: A. is called to attend a case of fracture, owing to the sudden illness of another, B., being away from home. A. attended to the case, and on B.'s return offered to hand over the patient to him. B., however, declines, and advises A. to continue in charge of the case.

A. does so, and on the completion of his attendance is asked to advise the patient's parent on another matter connected with the patient's health. Is A. by reason of the mode of his introduction to the family debarred from further attendance?

* * In the circumstances of the case A. would do well to consult B., and be guided by his advice.

PRIVATE DISPENSARIES AND CLINICS.

ENQUIRER writes to say that he proposes to open a dispensary for diseases of women at which he would attend on two days a week from 11.30 to 1.30, his object being to give advice and treatment gratis to women unable to pay who suffer from gynaecological complaints, and he asks whether it would be in accordance with medical etiquette if he were to send a letter to this effect to the medical practitioners in the neighbourhood, and further, whether he might enclose with it a copy of his testimonials.

* * If there is any need for a dispensary for diseases of women in the city where "Enquirer" lives he may try to establish it with the aid of the medical profession and other influential citizens, but it must be controlled by a properly constituted committee, and the staff must be elected in the recognized way. The establishment of a private dispensary cannot be approved.

The Services.

ROYAL ARMY MEDICAL CORPS (TERRITORIAL).

LAST YEAR'S TRAINING.

THE Army Council has intimated to general officers commanding that the working of the Territorial Medical Service in last year's training season reflects great credit upon all concerned, for its thoroughness in face of the many difficulties inseparable from the early stages of reorganization. The reports of administrative medical officers have been examined under the heads of the Medical Service with regimental units, camp sanitation, the training of field medical units, and general hospitals; and suggestions are made for future guidance.

MIDLAND DIVISION.

The First Mounted Brigade Field Ambulance, First Field Ambulance, and Second Field Ambulance of the South Midland Division, and First Southern General Hospital held their first church parade on Sunday, March 28th. The units, under the command of Colonel Whitcombe, marched from the R.A.M.C. head quarters at Witton to St. Martin's Church, Birmingham. They then marched to the drill hall in Thorp Street, where General Raite inspected the parade.

FIRST LONDON DIVISION.

With reference to the prize distribution in connexion with the First London Division, R.A.M.C. (L.F.), recorded at page 822 of our issue for March 17th, Lieutenant Colonel Harvey has sent us a communication, from which it is to be gathered that the premises in Calthorpe Street are not, strictly speaking, the head quarters of the Division. The Division has six units, and though four of these have their head quarters in Calthorpe Street, the other two have separate premises for their head quarters. The units of the First London Division having their head quarters in Calthorpe Street are the Third London Field Ambulance, the First London Sanitary Company, and the First and Second London General Hospitals. On the other hand, the First and Second London Field Ambulances have their head quarters in Bunhill Row, E.C., and Shaftesbury Street, E.C., respectively. It is hoped that eventually a new head quarters will be established for the whole of these units together.

Public Health.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Torough of Bacup.—The estimated population of Bacup in 1903 was 24,600. The birth-rate was 21.8, the death-rate 15.2, and the infantile mortality-rate equal to 104 per 1,000 births. We are glad to find that it is the intention of the corporation to push forward the conversion of pan-closets to water-closets. To encourage this conversion, part of the cost is to be paid by the corporation, and no charge is to be made for water supplied to one water-closet in each house. The medical officer of health (Dr. John Brown) draws attention to the house fly as a cause of diarrhoea, and urges that, with a view to lessening their number, every effort should be made to remove horse manure from the proximity of houses. He suggests that fowls should be kept, "for they eat the flies and the larvae before they develop into flies." The increasing number of exemptions from vaccination which is occurring in Bacup is a distinct menace to the district. In 1902 there were 560 births, and 51 exemption certificates were granted; whereas in 1903, with 537 births, there were 220 exemptions. There are probably at the present time in Bacup between 600 and 700 unvaccinated children under 5 years of age.

Obituary.

PATRICK BLAIKIE SMITH, M.D.

CONSULTING PHYSICIAN TO THE ROYAL INFIRMARY, ABERDEEN.

It was with much regret that we have to announce the death at San Remo on March 24th of Dr. Blaikie Smith. The immediate cause of death is understood to have been influenza, but his death will occasion no surprise, as Dr. Smith for some years back had been in feeble health, and those of his friends who saw him last summer noticed that he did not look so well as usual; the loss of his only son at San Remo last year was a sad blow to him.

Patrick Blaikie Smith was born in 1849 in Aberdeen, where his father was City Architect. He studied at Aberdeen University, and took the degrees of M.B. and C.M. in 1870, with highest honours, and that of M.D. in 1878. After graduation, he proceeded to London, and was for some time one of the residents at Middlesex Hospital.

He returned to Aberdeen in 1872, and started private practice; in 1873 he was appointed Assistant to the then Professor of Chemistry, Professor Brazier; this post he held for three years, and old students of the university will remember the help he was to them in the practical chemistry class, being a worthy demonstrator to one of the neatest experimenters in chemistry the university has ever had. About this time he was one of the dispensary physicians, which position he held for eight years. His connexion with the Royal Infirmary began by his being appointed Anaesthetist, which post he held until his appointment as Assistant Physician in 1886; in the following year, on the death of Dr. Beveridge, he was raised to the full Physicianship, and was one of the Lecturers on Clinical Medicine. He was an able lecturer; he gave much attention to clinical teaching in the wards, instilling into the students the importance of strict accuracy in the observation of all symptoms. In 1889 Dr. Smith was appointed Examiner in Pathology in Aberdeen University, which post he held for several years. On the death of Professor Smith Shand he was a candidate for the vacant chair. He held, while in Aberdeen, appointments as Physician to various institutions in the city. He was very successful in private practice, and gained the esteem and regard of his many patients by his devotion to his work. A keen volunteer, he held the rank of Surgeon-Major to the 1st Volunteer Battalion Gordon Highlanders, and was one of the first medical officers to take up the teaching of ambulance work to volunteers.

In 1895 Dr. Smith's health broke down, and the cold east winds of his native city during the winter months compelled him to reside in a more congenial climate; this he found in San Remo, where he spent the winters, returning to Nairn for the summer months. In both places he built up a good consulting practice. Among articles contributed by him to the medical journals were papers on Tumours of the Brain, one on the Treatment of Acute Pneumonia by Ice Cradling, published in the JOURNAL in 1895, and on Peripleuritis.

While practising in Aberdeen, Dr. Blaikie Smith was a well-known figure, of spare build, scorning the wearing of an overcoat, even on the coldest day in that "east-windy" city. He got through an enormous amount of work connected with his private practice and public appointments, and was a great favourite with his patients, and it was with much feelings of regret that they received the news that he had to leave them on account of ill-health. With the students he was exceedingly popular, both as an examiner and lecturer; in the former capacity he was, while searching in his methods, exceedingly fair, never worrying the student with unnecessary questions. Methodical and punctual in all things, he tried to inculcate these virtues into his students, in whose welfare he took a keen interest, and by his old students, all over the world, the news of his death will be received with much regret.

Dr. Blaikie Smith is survived by a widow (a sister of Sir Patrick Manson) and two daughters. As already stated, his only son died at San Remo last year.

LIEUTENANT-COLONEL TUOHY, M.D., M.Ch.,

M.A.O.R.U.I., I.M.S. (RET.).

LIEUTENANT-COLONEL TUOHY, who died at Brighton, in his 54th year, on February 22nd, was a distinguished officer of the Indian Civil Service, having taken part in the last

Afghan campaign, for which he held the medal. He was stationed for a year at Kandahar after its occupation. He held the position of Police and Civil Surgeon for seventeen years under the Government of the North-West Provinces, and was the first Superintendent appointed to the Ramsey Hospital, Naini Tal, the largest hospital for Europeans in Northern India. Here he held the post of Police and Civil Surgeon, which he also filled at Allahabad, Agra, and Saharanpur. At Agra he was Superintendent of the Medical School and the Colvin and Lady Dufferin Hospital, being a member of the North-West Provinces Committee of the Lady Dufferin Fund. On many occasions he received the official thanks of the Government for the manner in which he performed the duties of civil surgeon. Of late years, after his retirement from the service, he followed private practice at Hove, Brighton.

During his service in India he earned for himself a high character for his administrative abilities, to which on several occasions testimony was given by the heads of the Indian Medical Department. His unexpected death occurred after a comparatively brief illness, and has been greatly regretted by all his old colleagues in the service and by a wide circle of friends, for he was a man whose personal character endeared him to all who knew him. He was, in the words of one of the chiefs of the Indian Service, "a thorough gentleman, conscientious, and tactful in his dealings with others."

FREDERICK HALLAM HARDY,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

CAPTAIN FREDERICK HALLAM HARDY, of the Royal Army Medical Corps, died at Aden on March 8th. He was one of three medical officers engaged in investigations on Lake Nyassa with the view of checking the spread of sleeping sickness in Nyassaland. It was found last December that Captain Hardy had become infected with trypanosomiasis, but in what way is not precisely known.

Captain Hardy, a man who long since proved his claim to the esteem of the profession to which he belonged and his value to the country which he served, died on his way home, and his name must be added to the honourable roll of those who, courageously facing obvious dangers, have finally succumbed in the cause of scientific progress and useful human knowledge. Captain Hardy, though he had reached the age of 36, was a comparatively junior member of the Royal Army Medical Corps, for he joined it only when he had already seen plenty of active service in other capacities, and had established a reputation as an energetic and scientific observer.

His general education Captain Hardy received at Shrewsbury, proceeding afterwards to Guy's Hospital. In 1896 he obtained the diplomas of M.R.C.S., L.R.C.P., and some two years later received appointment from the Foreign Office as Surgeon in British Central Africa. Proceeding to his post he was told off almost immediately on arrival to take part in the expedition in Southern Angoniland, and from these operations issued with a medal and a clasp. The following year again saw him engaged in a military capacity in connexion with the operations against Nkamba, which won him a second medal and a second clasp. In 1900 he was gazetted to the Royal Army Medical Corps, and in view of his experience of tropical conditions was appointed to the King's African Rifles, and with this corps took part in the expedition on the West Coast of Africa. On this occasion he again proved himself a valuable officer, and his name was mentioned in dispatches and a clasp added to his medals. By this time he had in four short years taken part in as many as three distinct expeditions in the field against more or less savage tribes, and in conditions infinitely trying to his own health and to those of the men in his charge. This would have been a good record for any man even if spread over the total period of an officer's career, but it did not complete Hardy's work and experiences in this direction. Only a year later he was to be found once more on active service—this time on the East Coast—as one of those engaged in the wearisome, dangerous, and exhausting operations in Somaliland. They did not end for two years, and Hardy, having been present at the action at Jubbelti as well as in the field throughout, received two more clasps. When the Colonial Office took over British Central Africa it secured him for service in that locality, and got him seconded from the Royal Army Medical Corps

in 1906. From that date onwards until shortly before his death he was engaged in carrying out scientific researches on the general subject of tropical disease and was doing most excellent work. When the fact of his infection with the organism of sleeping sickness became obvious it was decided that he should be sent home to England for treatment, in charge of Dr. Kinghorne of the Liverpool School of Tropical Medicine. The list of deaths from sleeping sickness among Europeans is at present but a short one, and it is a notable fact that two contributions to it should already have been made by the Royal Army Medical Corps. The first was that of Lieutenant Tulloch, the circumstances of whose death were of a kind closely corresponding to those now recorded. On the other hand, Captain Hardy is probably by no means the first of his family to die in the service of his country, for he comes of a military stock, his father, General Hardy, being an old Mutiny veteran, and four of his brothers holding commissions in the army and navy.

The death occurred on March 23rd of Dr. CHARLES COATES, of Bath, at the age of 85. He qualified in 1851 and obtained the degree of M.D. Aberd. in 1856. Dr. Coates was a Fellow of the Royal College of Physicians of Edinburgh and of that of London. He settled in Bath soon after obtaining his degree and had resided there ever since, being actively engaged in practice until about ten years ago. He was for many years one of the honorary physicians of the Royal Mineral Water Hospital, and at the time of his death was the second oldest governor of that institution. He had also been physician to the Royal United Hospital, and when he resigned in 1882 he was appointed consulting physician. He rescued the Blue Coat School in Bath from a position of serious difficulty by a timely gift of £1,000, and recently presented a similar sum to the Royal College of Physicians of London to found a prize.

Dr. ARTHUR ROBERTS, whose death at Eltham on March 19th is announced, practised for many years in Kensington. He was born in 1838, entered St. George's Hospital at the age of 17, and obtained the diploma of M.R.C.S. in 1859; in 1861 he took the diploma of L.R.C.P. Lond., and in the same year entered into partnership with the late Mr. J. J. Merriam of Kensington, with whom he continued to work for twenty years. Dr. Roberts was Surgeon to the Kensington Dispensary, and earned the gratitude of the patients there by his kindness and skill. He had a house at Ramsgate, where he sought change and relaxation from the heavy calls of a large practice in Kensington. After his retirement he took a house at Eltham, spending his time between that suburb and Ramsgate. Last November he suffered a great bereavement in the death of his wife, and within four months was laid to rest at her side in the churchyard of the parish of St. Lawrence, under the shadow of the old church he loved and in which he was a constant worshipper.

DEATHS IN THE PROFESSION ABROAD.—Among the members of the medical profession in foreign countries who have recently died are: Dr. Vittorio Liebmann, Physician to the Civil Lunatic Asylum at Trieste, aged 49; Professor Paulin, President of the German-Chinese Medical School at Shanghai; Dr. Berendi Vedeler, a well-known gynaecologist at Christiania, aged 72; Dr. Karl Seggel, of Munich, an ophthalmologist of considerable reputation; Dr. Prawossud, Lecturer on Ophthalmology in the University of Moscow; Dr. Ugolino Mosso, Professor of Materia Medica and Experimental Pharmacology in the University of Genoa; Dr. D. W. Brower, Professor of Neurology and Psychiatry in the Rush Medical College, Chicago; Dr. Paul Mannoix, one of the leading surgeons of Geneva, and author of numerous contributions to surgical literature, aged 73; Dr. Thaddeus Asbury Reamy, formerly Professor of Gynaecology in the Medical College of Ohio, now the Medical Department of the University of Cincinnati, aged 79; Professor Rudolf von Renvens, Director of the Moabit Municipal Hospital, Berlin; Dr. Ludwig von Thanhofer, Professor of Descriptive Anatomy in the University of Buda-Pesth, and author of various works on subjects connected with his speciality, aged 64; and Dr. Anton Friedlidsky, formerly assistant to Hyrtl of Vienna, and an intimate friend of that famous anatomist, aged 75.

Letters, Notes, and Answers.

BRITISH MEDICAL ASSOCIATION AND BRITISH MEDICAL JOURNAL.

THE offices of the British Medical Association and of the BRITISH MEDICAL JOURNAL are at 429, Strand, London.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 429, Strand, London, W.C.; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Office, 429, Strand, London, W.C.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Atiology, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, London*.

TELEPHONE (National):
2531, GERARD, EDITOR, BRITISH MEDICAL JOURNAL.
2530, GERARD, BRITISH MEDICAL ASSOCIATION.
2534, GERARD, MEDICAL SECRETARY.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL, and not at his private house.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

AD REM asks for suggestions in the treatment of a woman aged 50, who had been suffering from "noise in the head" for some months, following what appears to have been an attack of influenza of a gastric type. Bromides, cannabis indica, and ichthyol are among the drugs tried hitherto, but without effect.

ANAESTHESIA IN MIDWIFERY.

CHLOROFORM asks as to the safest form of anaesthetic and the best method of application to use in country midwifery practice, when called upon both to give the anaesthetic and to apply forceps, etc., when far removed from medical assistance. Is Junker's apparatus widely used for this class of case?

*. A good way is to crumple up a handkerchief, put it in a tumbler, sprinkle chloroform on it, and bid the patient hold it over her mouth and nose. As soon as her muscles become relaxed the tumbler will fall away.

gentle red red PEDICULI CAPITIS.

5677 asks respecting the chances of nits in the hair coming to life or otherwise. Parents often say they are "dead" nits. Does the use of, say, white precipitate ointment kill the nits? or only the lice?

*. The chances are that a good many are not dead. To a great extent the idea of parents that the nits are "dead" is a survival of an old belief handed down from Aristotle—namely, that nits are sterile. This notion was exploded by the Dutch naturalist, Leeuwenhoek, the father of bacteriology (1632-1723); but, his crucial experiment notwithstanding, both the people and the medical profession held on to the dictum of Aristotle. Even unto the present day people still hold that some persons "breed lice," as they term it. The use of white precipitate ointment does not destroy the nits, but only the lice. Any sticky oily preparation suffices for the latter purpose, the respiratory tracheae of the insects being in this way obstructed, with asphyxia as a result.

ANSWERS.

5690.—A regimental medical officer (T. Force) who has not transferred to the R.A.M.C. wears the same uniform as the other officers of the regiment, except that he wears the medical belts instead of the regimental.

W. G. J.—The name of Professor Carl Spengler of Davos is associated with the treatment of pulmonary tuberculosis by means of a mixed human and bovine tuberculin. It was described by him under the title "Ein neues immunitäts erzeugendes Heilverfahren der Lungenschwindsucht mit pelsucht Tuberculin," in the *Deutsche medizinische Wochenschrift*, No. 31, 1904, and No. 31, 1905.

THE DESTRUCTION OF FLIES.

JOHANNESBURG.—It is more or less useless attacking flies in their adult stages, for they are no sooner destroyed than others come and take their place. The only effectual measure is to abolish their breeding places, which, in the case of flies that come into houses, are manure heaps or smaller faecal collections. In dealing with towns this must be seen to by the sanitary service, as it is practically useless for one person to take action if others do not. Fumigating, provided the windows of a house are all shut, will of course destroy the flies present at that time. McDougall's or the X-L-A-I fumigators used for destroying insect pests in vinerias are efficacious for common flies as well. Of course, servants, children, and animals must all be made to leave the rooms during the fumigation. With proper ventilation next day any small soon disappear.

CLEANING DENTAL PLATES.

COONOR writes: With reference to the note on p. 444, of the BRITISH MEDICAL JOURNAL of February 13th, very many years ago I found great difficulty in cleaning my plate, even when using soap, powder, and a hard nailbrush. Accidentally, I found that by using a cleaned boiled rag and a little soap in a basin of water I could clean it perfectly and quickly with the greatest ease. The rag must not be folded up as a sponge, but as a single layer between the plate and fingers. I then found that I could clean my teeth with a wet rag held between the finger and thumb, much better than by using a toothbrush. I am told that natives of India always clean their teeth with the forefinger and then polish them with a chewed twig. Also they invariably wash out the mouth and clean the teeth immediately after eating. If European children could be taught to clean their teeth (each time after eating) in this manner, their teeth would soon improve.

ARTIFICIAL RESPIRATION.

WHEN Professor Schäfer first described his method of performing artificial respiration on persons apparently drowned, he directed that a folded coat should be placed under the lower part of the chest, but in his latest directions—those which formed the appendix to a report made by a special committee of the Royal Society of Medicine in 1908 to the Commissioner of Police—this instruction does not appear. There seems reason to believe that the folded coat was never intended to be regarded as an intrinsic part of the system, and that its object was merely to make it easier to prevent entry of air being obstructed by contact of the patient's mouth with the ground. By the method as now practised, this object is effected by leaving the patient's head flat on the ground, but turned at right angles to the body. It is believed that the use of the coat has been abandoned in order to reduce the system to its simplest and most essential features, and to ensure commencement of the movements by which respiration is induced at the earliest possible moment. To this end it is also directed that no time shall be lost by removing or loosening clothes.

LETTERS, NOTES, ETC.

ANOTHER APPEAL TO MASONS.

DR. WILLIAM WILSON (Secretary, St. Luke's Medical Lodge of Instruction, 184, Goldhawk Road, W.) writes: May I once again appeal to medical men, and medical Freemasons in particular, for votes for the Masonic Charities? At the forthcoming elections in April there are two medical candidates for the Royal Masonic Institution for Boys. Votes for either institution are equally valuable, and will be gratefully received and acknowledged by me.

A CORRECTION.

In an account of the meeting of the Clinical Section of the Royal Society of Medicine on March 12th, note was made of a case of ascites shown as cured by permanent drainage through the femoral ring. The exhibitor of this case was Dr. W. E. Wynter, not A. E. Wynter as previously stated.

A DISCLAIMER.

DR. J. DULBERG (Manchester) desires to disclaim any responsibility for the circulation of a testimonial to a vacuum cleaner which appears to have been issued in Manchester. He gave the testimonial to the company as a member of the public, and enjoined upon the company's representative that the testimonial should not appear as emanating from a medical man, and particularly directed that no initials should appear after his name. The latter part of the injunction was kept, but the testimonial issued as a circular is headed, "Striking testimonial from a prominent doctor and J.P. of the city of Manchester." Dr. Dulberg is taking steps to ensure that the circular shall be withdrawn until the objectionable words are deleted.

SPIRITUAL HEALING.

DR. ARTHUR KING (Faucesmith, O.R.C.) writes: An able and expositive sermon, by an Anglican priest, on Faith or Spiritual Healing, quickened an interest in me, which your last article (January 9th, 1909) on that subject has further reinforced, since the matter was presented at the consulting-room door, instead of at the study. Christian Science (like hypnotism formerly) has become discredited, because whatever spark of truth it possesses has become overlaid and obscured by ignorant clap-trap and fraudulent quackery. Few medical practitioners will be inclined to dispute the power as good or evil agents, within certain limits, of auto-suggestion,

faith, external influence, surroundings, spells, etc., on health and on the course of disease. The very real existence of such influence will be mostly admitted as a fact. I shall avoid all pretence at scientific discussion of the subject, involving as it does the complexities of super-sensual psychology, and content myself with superficially touching on the practical aspect of the movement as it affects us. The question before us as a profession is as to our attitude toward the proposed partnership or co-operation of medical practice with the Church or allied societies, such as the Church and Medical Union and Society of Emmanuel. We need not consider as to whether it would be to the material interests of its members or the profession corporately, since we owe our first duty to our patients, to which consideration the issue is narrowed. It seems doubtful if the invocation of spiritual aid by or with the medical attendant would—suggesting the idea more of division than addition—strengthen the faith of the patient in his own recuperative powers, or in the material or spiritual forces at work outside of him, and so conceivably rather lessen than enhance the powers of "mental healing," to use the title of Dr. Chandler's book. Divided responsibility, like the two stools, introduces an element of precariousness into the situation. Should the patient have a happy issue out of affliction, the most valiant and glorious practitioner would scarcely take all credit to himself, but on the other hand, should the termination not be so favourable, it might lead to bitter recriminations and mutual undervaluation between the parties concerned. The very old story about the sinking ship and the prelate seems a propos, and I may be allowed to repeat it. The prelate asked the captain if all was being done to save the ship, to which the skipper replied that all the pumps were working and that nothing remained but to "trust in Providence." The prelate merely said: "Has it come to that?" Might not our patients in comparable circumstances take a similar hopeless view of their condition were we as a profession to indulge in more than a nodding acquaintance with this latest propaganda?

DR. DAVID A. ALEXANDER (Clifton, Bristol) writes: Your discussion of recent attempts to establish ministries of healing recalls a passage in the writings of Stokes of common interest to all who have a regard "as well for the body as the soul." In his work, *Diseases of the Heart and Aorta* (1854), he describes in detail (p. 23) a case of what he regarded as pericarditis with pneumothorax; and, upon its protracted convalescence, throws into a footnote this comment:

"There is a circumstance connected with this case worthy of being recorded as illustrative of the influence of the depressing emotions in retarding the processes of cure in disease. After the disappearance of the signs of air, I was in hopes that the patient would be speedily restored to health; but day after day elapsed, and no progress seemed to be made in the organizing process. The rubbing sound remained unchanged, notwithstanding all the means I could devise to bring the case to a successful issue. I observed that the patient was depressed and melancholy, and, on inquiring from his wife whether he had any mental suffering, I was told that he had great fears as to his spiritual state, and was full of doubts on many points of his religious belief. Under these circumstances, I asked a clergyman, distinguished for his talent and eloquence, to visit my patient. This interview was followed by the best results. Next day the rubbing sounds had become softer; the visit was repeated, and on the third day all morbid signs had disappeared. That the process of organization in this case was prevented or delayed by the depressed condition of the patient's mind there can be no doubt. The recovery of the patient was complete."

There are not a few clinical histories in which might be included the factor which Stokes authenticates.

THE CAUSATION OF INGROWING TOENAIL AND THE LOCATION OF GOIT.

DR. G. ARBOUR STEPHENS (Swansea) writes: Mr. Edward C. Masser's letter (p. 823) loses some of its interest from the fact that he did not see for himself in what position the South African native places his toes, when he is lying on his side. The question, "Why do not bootless natives suffer from ingrowing toenail?" may be answered by another question: "Why does not every lady who wears tight-fitting and pointed boots suffer from toe trouble?" My experience has been that it is people who are nervous or who are in an irritable state of mind that dig their toes into the bed; highly-strung children are also inclined to the same habit.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE
BRITISH MEDICAL JOURNAL.

	£	s.	d.
Eight lines and under	—	—	0 4 0
Each additional line	—	—	0 0 6
A whole column	—	—	2 13 4
A page	—	—	8 0 0

An average line contains six words.

All remittances for Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 425, Strand, London, not later than the first post on Wednesday morning preceding publication; and, if not paid for at the time, should be accompanied by a reference.

N.B.—It is against the rules of the Post Office to receive letters at *Postes Restantes* addressed either in initials or numbers.

Remarks

ON

PARALYSIS OF THE MOVEMENTS OF
THE TRUNK IN HEMIPLEGIA,

AND THE MUSCLES WHICH ARE AFFECTED.

BY THE LATE CHARLES E. BEEVOR, M.D., F.R.C.P.,

LATE PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE,
AND TO THE GREAT NORTHERN CENTRAL HOSPITAL.

This paper is intended to show that in some cases of hemiplegia—let us say left—the trunk muscles of each side act weakly when they take part in left-sided movements, and the same muscles act normally when they take part in right-sided movements; also that the movements of the trunk requiring bilateral action of muscles are very little, or not at all, affected. The question is discussed of the change in representation of one and the same group of muscles from one hemisphere to the other accordingly as they act in right-sided or left-sided movements; and also the question of the representation of movements requiring bilateral action of muscles in one or both hemispheres.

The condition of the muscles of the trunk in hemiplegia and the question whether the movements in which they take part are paralysed or not has always presented considerable difficulty. In this paper I propose to describe a case of hemiplegia in which certain movements of the trunk were defective, so that, amongst other defects, the patient fell towards the hemiplegic side in trying to sit up; to analyse the muscles which take part in these defective movements; to compare these voluntary movements with those produced by morbid conditions in man, and with those elicited by cortical electric stimulation in animals in reference to representation of the movements in one or both hemispheres; and to describe the methods of ascertaining these defective movements in man.

The patient was under my care at the Great Northern Central Hospital. According to the notes of Mr. Clayton, the house-physician, he was aged 52, married, a confectioner, but twenty years ago was a soldier in India. He had had gonorrhoea, but there was no history of syphilis and no history of alcoholism. He had a fall from a bicycle a week before the onset, which was sudden, without loss of consciousness, and he lost power in the left arm and leg. On admission, there was no facial paralysis, the ocular movements were normal, the tongue when protruded deviated slightly to the right, but he had more difficulty in putting the tip against the left cheek than the right. There was complete loss of power in the left upper and lower limbs, and the joints in the left lower limb were rather rigid. Sensation over the whole of the left half of the body and face and the left limbs was diminished to tactile and painful stimuli. The deep reflexes were about equal on the two sides, while the superficial abdominal reflexes were diminished on the left side, and the left plantar reflex gave extension of the big toe when the sole of the foot was stimulated on the outer side, and flexion on the inner side. There was reduplication of the first cardiac sound at the apex of the heart; the blood pressure was 200 to 215 mm. of Hg; urine 1016, no albumen. There was no optic neuritis.

In sixteen days from the time of onset he began "to recover movement in the left upper limb, but there was no return in the leg till after another five days. In about twenty-eight days after onset he had recovered all movement of the upper limb, including those of the hand and elbow, and he could advance and abduct the shoulder, but he had no power to elevate the left shoulder girdle. In voluntary coughing the left latissimus dorsi contracted much less than did its fellow on the right, though in adduction of the humerus the left latissimus dorsi acted almost normally.

When put on the sitting position in bed the patient fell over to the left side, and when he had fallen to that side he was unable to raise himself to the vertical position again; but if he was inclined to the right, so that his centre of gravity fell to the right of the spine, he could keep himself in that position. On testing the recti abdominis when lying on his back, by making the patient flex the head and neck, the muscles contracted with equal strength, but the right rectus began to contract before the left, also, on testing the erector spinae in extending the spine with the patient lying on his face, both muscles contracted equally, but the right moved first. When lying down lateral abduction of the trunk against resistance was noted to be stronger towards the right than to the left.

In another week he had recovered almost normal power in the left limbs with the exception of elevation of the left shoulder; also in forced inspiration elevation of the left shoulder was less than on the right.

On further testing the movements of the head and neck, it was found that in lateral adduction of the neck to one shoulder the trapezius (clavicular fibres), splenius capitis, levator anguli scapulae, and sterno-mastoid of that side took part, but the movement to the right shoulder was stronger than that to the left. In rotation of the head and neck to one side, the rotation to the right, in which the left sterno-mastoid and trapezius act with the right splenius capitis and levator anguli scapulae, was stronger than rotation to the left. Therefore the left sterno-mastoid and trapezius take part in the parietic left-sided movement of adduction of the head and neck to the left shoulder, the same left-sided muscles take part in the strong normal right-sided movement of rotating the head and neck to the right side.

About two months after the onset he could sit up without falling to the left, and the strength of the lateral movements of the trunk on the two sides was measured. The patient was seated on a stool and the thighs were fixed by an assistant so as to have a horizontal base line. A jack-towel was passed over the patient's left or right shoulder, and was connected to a traction dynamometer, which was fastened to a fixed point. Starting from the vertical position, lateral traction to the left by the patient gave 13 kilograms and to the right 18 kilograms, and in a second trial 18 and 22 kilograms respectively.

The patient was then inclined to the left with his trunk at an angle of 45° to his base line, and he made traction on the dynamometer to the vertical position. On the second trial the grams, while from the right inclination towards the vertical line the force was 22 kilograms; on a second trial the figures were 12 and 20 kilograms respectively.

The difference between the two sides (4 kilograms) in the first set of observations was not great, but the measurement was made two months after the onset, when the patient had considerably recovered. In the second set the difference was much more (8 to 9 kilograms), and to avoid the error of the difference being due to a left-sided movement, a healthy man was tested, and it was found that the movements on the two sides gave the same strength.

With regard to the pathology of the case, the lesion was probably a syphilitic arteritis, causing thrombosis of the branches from the anterior choroid artery to the posterior limb of the right internal capsule, so that the lower limb was affected more than the upper limb, which recovered first, the trunk muscles were unusually severely affected; there was also some slight left hemianæsthesia. The movements of the face were unaffected, and this would be due to the fibres near the genu of the internal capsule, which on electric stimulation give movements of the face, being supplied by the posterior communicating artery, which in this case was apparently not involved.

The severe paralysis of some of the left-sided movements of the trunk, the loss of elevation of the shoulder, the slight affection of the hand movements, and the more complete paralysis of the leg as compared with the arm, are exactly the symptoms given by Horsley and Schäfer after removal of the right marginal gyrus; and it would seem that the fibres of the internal capsule, which come from the marginal gyrus, must have been especially involved.

The patient was treated with potassium iodide. The patient recovered all the movements of the limbs and trunk, with the exception of the elevation of the left shoulder, which was still deficient three months after the onset.

In considering this case it is desirable first to ascertain the muscles which take part in the defective movements and are responsible for their proper performance.

The patient fell over to the left side when he was put into the sitting posture in bed. Also when he had fallen over to the left side he was unable to raise himself from this position on his left side to the vertical mid-line.

A patient in the sitting position falls to the left, because the muscles which should counteract the action of gravity are paralysed, for in every unopposed movement in the direction of gravity it is the antagonists which act, and not the muscles which are the prime movers.

In the supine position, when the lateral movements are not influenced by gravity, the prime movers in the movement of the spine from the mid-line to the left are the left erector spinae and rectus abdominis, and the antagonists to this movement are the right erector spinae and rectus abdominis. Therefore when the trunk is in the vertical position, to prevent the spine falling from the mid-line to the left, owing to the action of gravity, the right trunk muscles (by which is meant the erector spinae, the rectus abdominis, and perhaps the oblique externus and internus) should contract, and their inability to do so shows that they are paralysed. In the same way, when the patient has fallen over to the left side, the muscles which should raise the trunk from that position to the vertical mid-line—that is, adduct from the left to the mid-line—are the right erector spinae and rectus abdominis, but in this case the patient was unable to perform this movement, owing to paralysis of these muscles for this particular movement. From the above it is seen

that the same muscles—that is, the right trunk muscles—take part in the unopposed movement in the direction of gravity, of abduction from the mid-line to the left, and also in the opposite movement against gravity of adduction from the left to the mid-line. The difference in the action of the muscles is that in the first case the muscles contract and gradually elongate to let the trunk fall to the left, and in the second case the muscles are elongated to start with and in contracting they gradually shorten and draw up the trunk to the vertical position. The simplest example of these two opposite movements is that of the elbow-joint. If the humerus be placed horizontally and the forearm be put vertically upwards at a right angle to the humerus, and if then the person be told to extend the elbow slowly, the triceps starts the movement, but as soon as the vertical position is passed and the forearm is acted on by gravity the triceps ceases acting, and the biceps and other flexors contract to prevent the forearm falling rapidly, and the muscles elongate gradually to their full extent. If then the elbow be flexed against gravity the same muscles, biceps and other flexors of the elbow, will contract and carry the forearm to the vertical position.

It is a question whether these two opposite movements are represented in the same part of the "motor" cortex, or whether the extensor movement is represented in the cortical extensor area of the elbow and the flexor movement in the flexor area; but as in the extensor movement in the direction of gravity the first action of the muscles is that of flexion to neutralize gravity, it seems that though the idea in the person's mind is that he is performing an extension movement, the movement is really being produced by gravity, and the rôle of the "motor" cortex is to cause just so much contraction of the flexors as will prevent gravity acting too quickly. To test this question in the arm it would be necessary to have a case of hemiplegia in which there was recovery of the movement of flexion, and paralysis of the movement of extension of the elbow, and then observe whether the movement of extending the arm in the direction of gravity could be performed slowly. In the case of left hemiplegia here described the inability of the *right* trunk muscles to prevent the trunk falling to the left under the influence of gravity was in marked contrast to the power with which the *left* trunk muscles could bend the trunk against resistance in the same direction. In fact, the weakness in the former movement corresponded to that in the movement of adduction from the left to the mid-line. In other words, when in the early stages the patient fell over to his left side and had not the strength to lift himself up again, he could carry the trunk from the mid-line to the left against resistance with very fair force, although normally the ratio of power of adduction from the left to the mid-line is to that of abduction from the mid-line to the left as 3 to 2, owing to the muscle being elongated and working at a greater advantage in the first case. This would make it probable that unopposed abduction of the trunk towards gravity to the left and adduction from the left to the mid-line against gravity were represented in the same part of the "motor" cortex.

The next question is, Are these movements of letting the trunk incline to the left and of drawing it from the left to the vertical position, which are accomplished by the right trunk muscles, right-sided or left-sided movements? It seems to me that they must be looked upon as left-sided movements, as they take place in the field of movement situated to the left of the middle line of the body, just as unopposed lateral inclination of the spine to the right and drawing of the spine from the right to the mid-line, that is, adduction from the right to the mid-line, must be looked upon as right-sided movements though they are performed by the left trunk muscles, which in this movement acted normally.

The fact that the loss of these two movements in the left field of action occurred in a case of left hemiplegia is strongly in favour of these movements being left-sided, and consequently of their being liable to be paralysed in a lesion of the right hemisphere.

The other movement which was deficient was that of abducting against resistance the spine from the middle line to the left, which was found to be weaker than the movement of adduction to the right. This movement from the mid-line to the left is performed by the left trunk muscles, especially the left rectus abdominis and erector

spinae, while the corresponding normal movement on the right side is performed by the right trunk muscles.

We have, therefore, in this case of left hemiplegia the *right* trunk muscles (1) acting weakly, or not at all, in the unopposed *left-sided* movement of preventing the trunk falling from the mid-line to the left, and in the *left-sided* movement of abducting the spine against resistance from the left to the mid-line, and (2) acting strongly and normally in the *right-sided* movement of abducting the spine from the mid-line to the right against resistance. Conversely we have the *left-sided* trunk muscles (1) acting strongly and normally in the *right-sided* movements of preventing the trunk falling from the mid-line to the right, and in adducting the spine from the right to the mid-line, and (2) acting weakly in the *left-sided* movement of abducting the spine from the mid-line to the left against resistance.

If it should seem anomalous that the right trunk muscles should be paralysed in a left hemiplegia, depending on a lesion of the right hemisphere, for left side movements and not for right, it must be remembered that we have examples in other muscles of a similar condition.

The right sterno-mastoid takes part in the right-sided movement of adduction of the head to the right shoulder as well as in the left-sided movement of rotating the head with the face to the left, and it was found in this case that there was weakness of the left-sided movement of rotation with preservation of the right-sided movement of adduction.

The above apparent anomalies disappear if in dealing with hemiplegia we always remember Hughlings Jackson's dictum, that the brain knows nothing about muscles but only of movements, and all that we have to take into account is, whether the movement takes place in the field of action on the right or the left of the antero-posterior mid-line of the body.

It might be thought that if a person in the sitting position starts from the extreme left lateral position and moves the trunk to the vertical position and thence to the extreme right lateral position against resistance, which might be applied by the hand of the observer acting against the right shoulder, he would perform one movement, as the same muscles—that is, the right trunk muscles—are acting throughout the movement. But from what was found in this case of left hemiplegia this movement cannot be looked upon as one movement. In this case the patient was quite unable to perform the first part of the movement from the extreme left to the mid-line, but he could perform the second part from the mid-line to the extreme right. We must therefore consider the first part as a paralysed left-sided movement and the second half as a normal right-sided movement. If this be correct, then the movement from the extreme left to the mid-line—adduction from the left—must be represented in the right "motor" cortex, and that from the mid-line to the extreme right—adduction to the right—must be represented in the left "motor" cortex.

Therefore if this movement be made continuously from left to right, there must be a change of the representation of the movement from the "motor" cortex of the right hemisphere to that of the left, when the mid-line is passed.

If this be so when the mid-line of the body corresponds to the vertical line, what would happen if the mid-line were inclined 30 degrees to the left of the vertical plumb-line? Will the presumed change of hemisphere take place when the spine reaches the mid-line (in a line with the sacrum) or when it reaches the vertical line—that is, will the whole of the movement from the extreme left to the vertical line be represented in the right hemisphere, or will the part of the movement between the mid-line and the vertical line be represented in the left hemisphere?

The following procedure will put the matter more clearly: A normal person sits on a plane inclined 30 degrees to the horizon, so that the right ischial tuberosity is an inch or two higher than the left, and the pelvis is consequently tilted to the left, and the mid-line of the sacrum and the spine is inclined 30 degrees to 45 degrees to the vertical line. The trunk is then placed in a position inclined laterally as far as possible to the left, and the person raises the trunk against gravity to the vertical position without altering the tilt of the pelvis. The right trunk muscles will then be felt to contract

throughout the movement, and we have to determine whether it is a right or a left sided movement. The movement from the beginning to the point where the spine is in a straight line with the sacrum—that is, the mid-line—must be considered to be a left-sided movement, and to emanate from the right cortex, while from the mid-line to the vertical line the movement must be considered right-sided, and to emanate from the left cortex.

We have, therefore, the same muscles producing an apparently similar movement throughout, but when this movement crosses the mid-line there must be a change of impulses from one hemisphere to the other, and the question arises—how is this change accomplished?

The advantage in the above procedure of tilting the pelvis and putting the mid-line of the trunk at an angle to the vertical line is that in the whole movement to be performed the weight to be raised remains constant—namely, lifting up the weight of the trunk against gravity; whereas, if the pelvis were on a horizontal plane, the first part of the movement, even if made against resistance, would be against gravity, and the second part in the direction of gravity, and this change would give an indication when the mid-line was passed. When the pelvis is tilted no such indication is present, and if the person closes the eyes, the only information which is sent to the cerebrum is that of the afferent impressions from the joints and muscles, and from the semicircular canals.

In every voluntary movement the mechanism is sensorimotor, and it is presumed that the cerebral hemispheres are kept informed by the afferent impressions concerning the relation of the spine to the fixed point of the sacrum and pelvis, and it would thus be determined, according as the movements required are left-sided or right-sided, whether the impulses should come from the right or the left hemisphere—for example, a movement required to carry the spine from the mid-line to the right would be, so to say, registered as a right-sided movement to be put into action by the left "motor" cortex. If this be correct, it would be another instance of how completely muscular movements are under the control and domination of afferent impressions from the muscles and joints, as is seen in locomotor ataxia, and in the important experiments of Sherrington and Mott,¹ who produced complete paralysis of the upper limb in a monkey by dividing all the posterior roots coming from it.

In the case of left hemiplegia here described it is important to note that the paralysis of the movements of the trunk was confined to those which were unilateral—that is, adduction and abduction of the spine—and it was found that in the movements of flexion and extension of the spine no difference in the strength of the rectus abdominis or of the erector spinae of the two sides could be made out; the only difference seen was that the muscles of the right side started the movement sooner than those of the left.

What light does experimental physiology and clinical observation throw on this subject?

From experimental physiology we have the movements which have been obtained in monkeys and in the anthropoid apes from electrical stimulation of the cortex and of the internal capsule. According to Sir Victor Horsley and the writer,² from stimulation of the internal capsule in the monkey no movement was ever seen in both recti or obliqui abdominis, but invariably movement restricted to the muscles of the opposite side, notably the rectus, was seen. From the result of excitation or ablation of the "trunk areas" in the marginal gyrus, Horsley and Schäfer³ considered that the same unilateral representation existed. Also in Grünbaum and Sherrington's⁴ experiments on the anthropoid apes the same unilateral result was obtained.

The movements of flexion or extension of the spine have not been obtained from electrical stimulation of one hemisphere. According to the experiments of Mott and Schäfer,⁵ who stimulated simultaneously the identical motor centres in both hemispheres for the movement of rotation of the head and eyes to the opposite side and upwards or downwards, upward and downward movement of the eyes could be obtained, and also presumably of the head, though no mention is made of the movements of the head from this bilateral stimulation. What holds good with regard to flexion and extension of the head, would probably apply to the movements of flexion and extension

of the spine, and this would postulate that impulses would have to emanate from the centres of both hemispheres to produce a bilateral movement. This might also explain why, in the case of left hemiplegia here described, the contraction of the left rectus abdominis and of the left erector spinae occurred later than on the right side in the movements of flexion and extension of the spine. If these bilateral movements are represented in those cortical centres of both hemispheres which preside over the unilateral abductor movements of the spine, it is necessary to assume that the impulses subserving bilateral movements take a different course in the internal capsule to that followed by impulses subserving unilateral movements; otherwise a lesion of one internal capsule, say the right, would block not only the latter but the former set of impulses, with the result that impulses subserving bilateral movements from the left hemisphere only would succeed in passing, and a bilateral movement would be converted into a right unilateral movement. In the present case, although the unilateral abduction to the left was weaker than to the right, in flexion and extension of the spine there was no difference in strength of the two recti and erectors, but only a delay in time of the left-sided muscles.

On the other hand, there seems no doubt that some bilateral movements are represented in each hemisphere, so that they are produced by stimulation of the centre in each hemisphere alone. An example of this class of movement is bilateral action of the vocal cords which are put into action by stimulation of the cortex of either side.

In favour of both the recti abdominis muscles being represented in each hemisphere so that the movement of flexion of the spine could be brought about through impulses emanating from one hemisphere is the observation made by Dr. S. A. K. Wilson on a case under the care of Sir W. Gowers at the National Hospital, in which both recti abdominis were seen to be convulsed in fits, which were otherwise unilateral. This might be accounted for either by both recti abdominis being represented in each hemisphere, or by the connexion through the corpus callosum between the "centre" for each rectus in each hemisphere being so intimate, that a fit starting in the "centre" of one hemisphere would easily pass to that of the opposite side.

Against the recti abdominis muscles being both represented in one hemisphere is the fact that only the muscle of the opposite side has been caused to contract by electric stimulation of one hemisphere.

The evidence as far as it goes seems to be in favour of both hemispheres being required to produce the action of both muscles, but at present it is not certain.

Taking the movement of the vocal cords at one end of the scale, and of the upward and downward movement of the eyes, or of flexion and extension of the spine at the other end, I would suggest the following explanation why the latter movements may require both hemispheres to produce action of both sets of muscles. The vocal cords have no movement which is independent of each other or is stronger on one side than on the other, the movements are either abduction, adduction, or shortening, and to ensure that they shall never act otherwise than together, the movements of both cords are represented in a centre in each hemisphere, and each hemisphere can act without the other. On the other hand, in upward and downward movement of the eyes there is every gradation through an arc of 90° between vertical upward movement and horizontal movement to one side—say the left—so that in vertical upward movement the centres in both hemispheres would act equally, but as the upward movement takes place more to the left less impulses would come from the left than from the right hemisphere, till finally, when the movements become horizontal the movements would be entirely from the right hemisphere. Also in the spine between flexion in the mid-line and pure abduction to the left against resistance there is every gradation of lateral flexion, and I have found, in performing the movement of flexing the spine against resistance, starting from the mid-position and flexing more and more to the left, that both recti contract, but the right less and less till, when the spine is flexed laterally in a plane which is 45° to the mid-line, the right rectus ceases to contract, and the left erector spinae

begins to act. It is a question, therefore, how much of these lateral movements is represented in both hemispheres: the movement of flexion in a vertical plane of 45° to the left of the middle line, where the right rectus ceases to act, is probably represented only in the right cortex, but it seems probable that the other movements between mid-line flexion and lateral flexion at 45° are represented also in the left cortex in diminishing degrees.

I would therefore suggest that while the bilateral movements of the vocal cords are represented in the motor cortex of each side, and can be made to contract by the impulses from one hemisphere only, the bilateral movements of the head and spine would require impulses from both hemispheres for their performance.

The movements of the tongue appear to be intermediate. For though from the observations of Sir Victor Horsley and the writer⁶ on the monkey, no difference between the actions of the two halves of the tongue in the movement of protrusion straight could be detected from stimulating the cortex of one hemisphere, yet the frequency in hemiplegia with which the tongue deviates to the paralysed side, when the patient tries to protrude it straight, is in favour of the movement being represented in each hemisphere, but with the muscles of the opposite side being more strongly represented than those of the same side, and not equally in each hemisphere, as in the case of the vocal cords; and although the tongue has lateral movements, the protrusion to one side has a different localization to that of protrusion straight, and the action of the two halves of the tongue in protrusion to one side—say, the left—consists of advancing of the right half and retraction of the left and is quite different to protrusion of the tongue straight, and is, perhaps, in a different category to the antero-lateral flexion of the spine to the left against resistance, where both recti abdominis have an action similar to that of flexing the spine straight, but with the left muscle acting stronger. Other bilateral movements which might be cited as imperfectly bilaterally represented are those of closing the eyelids and of elevation of the soft palate. In the paper already quoted,⁶ we found that in both these movements the closure of the opposite eyelids and elevation of the soft palate on the opposite side could be obtained without the movements of the same side by stimulation of one hemisphere; but as occasionally the movements of both sides were obtained from one hemisphere, we must look upon them as not pure causes of unilateral representation, but that the two sides are unequally represented in each hemisphere. An interesting point is that it is not possible to voluntarily elevate one half of the soft palate, and also that many people cannot close one eye without the other.

In reference to other clinical observations, I would refer to a case of double athetosis now under my care in the National Hospital, in which the movements are much more marked on the left side. On the left side there is frequent clonic contraction of the left trunk muscles, and especially of the left rectus abdominis and the left erector spinae; but there is no movement at all of the right rectus abdominis, and only a much less marked movement of the right erector spinae.

These clinical cases show that contractions of the abdominal muscles, limited to one side, can be produced by cerebral disease, and are thus in harmony with the results of electrical stimulation of the cortex of one hemisphere.

With regard to previous observers, Dr. Hughlings Jackson⁷ has expressed the opinion that in cases of hemiplegia—say the left—there is some very slight weakness of the lower part of the erector spinae muscle on the right side, the side of the cerebral lesion.

Of the other points of interest in this case, I might mention the action of the latissimus dorsi as a voluntary muscle and as an expiratory muscle of coughing. I have elsewhere⁸ shown that in hemiplegia, as a rule, the latissimus dorsi will act with its fellow of the other side as a muscle of voluntary forced expiration, when it will not act in the unilateral movement of adducting the humerus. In this case, however, the left latissimus did not contract so well on voluntary coughing as the opposite muscle, even when the left latissimus had recovered its power as an adductor of the left humerus. This case, therefore, differed from the majority of hemiplegias in this action of the latissimus dorsi, as well as in the arm recovering before the leg, in the elevation of the shoulder being the last move-

ment to recover, and also in the extensive degree in which the left lateral movements of the trunk were affected.

Another point of interest related to the question whether individual muscles or movements are represented in the "motor" cortex. The condition met with in this case of left hemiplegia, of the trunk muscles of each side acting strongly in right-sided movements, and weakly or hardly at all in left-sided movements, makes it very difficult, if not impossible, to explain how individual muscles could be represented in the cortex—a theory which has been upheld by some observers.

CONCLUSIONS.

In this case the patient in sitting up fell over to the left, and when over to the left he was unable to adduct the spine to the vertical position, but when in the vertical position he could push to the right more strongly than to the left. The muscle movements required for the prevention of falling to the left, and for adduction of the spine from the left to the mid-line are considered to be left-sided movements, and to be performed by the *right* trunk muscles; and adduction of the spine from the mid-line to the right against resistance is considered to be a right-sided movement, and also to be performed by the *right* trunk muscles. Therefore the right trunk muscles were paralysed or weak when they acted in left-sided movements, and were normal when they acted as right-sided movements. Conversely the left trunk muscles acted normally in right-sided movements (adduction from right to mid-line) and weakly in left-sided movements (adduction against resistance from mid-line to left). The movements of slow unopposed adduction of the spine from mid-line to left (that is, letting the trunk fall to the left), and of adduction of the spine against gravity from the left to the mid-line are probably localized in the same part of the "motor" cortex.

In making the lateral movement of the spine against resistance from the extreme left through the vertical position to the extreme right, the first half of the movement from the extreme left to mid-line is a left-sided movement, and the second half from mid-line to extreme right is a right-sided movement, and on the mid-line the cortical representation must change from the right to the left hemisphere. It is probable that this change is brought about by the afferent impressions from the joints and muscles of the spinal column.

The movements of the spine which were paralysed or acted weakly were unilateral; two sides taking part in the movements of flexing and extending the spine acted equally strongly though the muscles on the hemiplegic side acted later than on the other side.

From the above observation and that the movements of the trunk obtained by stimulation of the cortex or internal capsule are always unilateral, it seems probable either that the muscles of both sides are represented in the "motor" cortex of each hemisphere, or that the muscles of each side are represented in each opposite hemisphere, and that the association between them through the corpus callosum is very close. In bilateral movements generally the first arrangement is probably that of the representation of the vocal cords, and the second that of the flexors and extensors of the spine, while the bilateral movements of the tongue, of the soft palate, and of closing the eyes are intermediate, and muscles of both sides probably are represented in each hemisphere in varying degrees.

The method of testing and the movements which we should direct the patient to make are most important. It cannot be too strongly emphasized that it is not a question of which particular muscle is weak, but, in the first place, which particular movement is deficient or impossible to perform, and, secondly, which muscles take part in, and are paralysed for, this particular movement.

It has been shown in this case of left hemiplegia that the right rectus abdominis and erector spinae were paralysed when they acted as adductors of the trunk from the left to the mid-line, but they contracted normally when they acted as abductors of the trunk against resistance from the mid-line to the right. It would, therefore, be quite misleading to say that the right trunk muscles were paralysed unless we specified the particular movement, in which they took part, which was deficient.

The movements which we must ask the patient to perform must be unilateral, as the bilateral movements,

from reasons already given, are less liable than the unilateral movements to be paralysed in hemiplegia. The unilateral movements consist in abduction from the mid-line to the right and left, adduction from the right and left to the mid-line, and rotation of the spine with the face turned to the right and then to the left. All these movements should be tested with and without resistance, which should be applied by the hand of the observer against the patient's shoulder, and also both in the position of lying down and in that of sitting up in bed when this is possible, and particular notice should be taken in the latter position whether the patient is unable to prevent himself falling to one side.

A Clinical Lecture

ON

TRAUMATIC HEART DISEASE

AND

COMPENSATION FOR "ACCIDENTS."

DELIVERED AT GUY'S HOSPITAL.

BY

LAURISTON E. SHAW, M.D., F.R.C.P.,

PHYSICIAN TO THE HOSPITAL.

EVERY now and then some great discovery in pathology or in therapeutics leads us to change the point of view from which we regard certain diseases, in respect of either diagnosis or of treatment.

Recently there has been a social development, not a scientific discovery, which has led us to consider the causation of many diseases from a somewhat altered standpoint. I am referring to the tendency that there is now for all sorts of people to be insured against the results of accidents. In consequence of this habit, the possibility of an injury being the cause of any disease is much more before us as a profession now than it ever was before. The growing prevalence of insurance against accidents is probably responsible for what was to me a novel experience. Just before Christmas there were lying in adjacent beds under my care in Addison Ward two patients suffering from heart disease, each of whom attributed the symptoms from which he was suffering to an accident. This exceptional occurrence led me to choose as my subject for lecture to-day traumatic heart disease. And in introducing to you notice the question of traumatic heart disease by relating to you some of the particulars about these two patients, I propose to take the opportunity of offering for your consideration a classification of traumatism of the heart generally, then to draw your attention to some of the difficulties by which the profession which you are about to enter is assailed owing to the spread of insurance against accidents, and finally to ask you to consider some possible means of avoiding some of these difficulties.

I.—TRAUMATISM OF THE HEART.

There are three very different conditions in which injuries to the heart occur. First, there are the conditions in which gross and obvious injuries to the heart result from external violence. A man is cycling with his machine out of control; he meets and collides with a cart; the shaft penetrates his thorax and causes immediately fatal results. Other examples are those in which the buffer of a train breaking the sternum and the ribs leads to the heart being seriously injured by the bony fragments. Bullet wounds and stabs of the heart are also in this section—conditions, perhaps, of more interest, because they may afford an opportunity of surgical treatment if the injuries are not too extensive. Another interesting injury to the heart due to external violence is worthy of your consideration, inasmuch as you

may yourselves be responsible for causing it in attempts to aspirate the pericardium.

The essential feature of this group of cases is the obvious external violence. The patient seldom survives to present symptoms of heart disease.

The second group consists of cases in which there is a disruptive lesion of the heart, which is certainly not due to any external violence. The patients are found dead, and the muscular wall, generally of the left ventricle, is torn across, and the pericardium is full of blood. In such cases, as a rule, you would find obvious disease of the muscle of the heart, fibroid or fatty, which explains its rupture on such slight provocation. Every now and then it will not be quite clear that there is any obvious antecedent disease, although it seems almost certain that a muscle must be diseased before any internal pressure resulting from the ordinary circulation of the blood would cause it to rupture.

These may prove very interesting cases, because questions may arise as to whether the relatives of a person found dead under such circumstances are or are not entitled to receive compensation on the grounds that he has died as the result of an accident. Certain it is that in some of these cases the patient is found dead in bed, which makes it unlikely that a violent strain is necessary to produce such a rupture. At other times this condition has been found in the case of a man who was exerting himself to his utmost immediately before his death.

I come now to the third group, to which, perhaps, the title "traumatic heart disease" is alone properly given. Introducing you to this group, I will mention the few salient features about 4 cases which have come under my observation.

CASE I.

A young tram conductor, several years before admission, had had rheumatic fever, but believed himself since to have been in perfect health. One night two drunken passengers had to be expelled from his car. He struggled severely in throwing them out, and when he got home a little later, feeling rather exhausted by his efforts, he noticed a curious noise in his chest, and, calling his wife's attention to it, she also was perfectly certain that she could hear a loud noise in his chest which she had never heard before. He came the next morning to the hospital, and was found to have an extraordinarily marked musical murmur, diastolic in rhythm, all over the precordium. He was not suffering from any marked cardiac symptoms beyond that. Here was definite aortic regurgitation, apparently produced or increased by violent struggling; and we imagined that in the struggle he had torn or detached one of the semilunar aortic valves, and was consequently suffering from aortic regurgitation, at present thoroughly compensated.

CASE II.

A painter, 50 years of age, who at the age of 20 had syphilis, and a few years later rheumatic fever, believed himself to be in perfect health from that time until a few weeks before admission. When painting something high up, he slipped, fell, saved himself with a great effort as he fell, and immediately had cardiac pain and breathlessness. When admitted to the hospital, we found that he had aortic stenosis—a well-marked systolic thrill all over the right of his sternum—and distinct evidences of cardiac failure. In his case we imagined that his hypertrophied heart, which resulted from his aortic stenosis, to which he had done its worst extremely well for many years, was suddenly dilated as a result of the violent effort which he put out.

In both these cases you will see there was pretty clear evidence that the patient had already chronic endocarditis, and that the alleged injury was an injury to a diseased organ.

CASE III.

A sea cook, a little over 20 years old, perfectly well as far as he knew, and telling us that he had never had a day's illness in his life before, was on a voyage from London to Hamburg. Lifting a canldron of soup off the fire, the ship gave a sudden lurch, and, desperately afraid that the soup might upset and scald him, he put out all his effort to prevent this. He saved it, but immediately suffered from a very severe pain in his heart, and extreme condition of syncope; so that he was laid flat on his back, was kept on his back until the boat reached port, was immediately carried to the hospital at Hamburg, and remained there for many weeks, until it was thought safe for him to travel to England, when he came to the out-patient department at Guy's Hospital.

In his case we assumed, quite wrongly, as I shall show you in a moment, that his tremendously violent effort had ruptured a healthy aortic valve; and, under this impression, this case was shown at the Clinical Society. Years afterwards I met this case again in the hospital as an in-patient; and he then told me that, after my careful

inquiries about his previous health—which, you remember, I thought established the fact that he had not had a day's illness in his life before—he went home, and, inquiring from his mother, he was told that he had a bad attack of St. Vitus's dance as a small child, which he had quite forgotten. This case, therefore, is strictly analogous to the other two. I was wrong in assuming that it was an example of the rupture of a healthy valve. There can be little doubt now that this man's valve was affected by his chorea, and that his great exertion ruptured a diseased valve.

CASE IV.

A former pupil of mine was unwisely touring with a heavy motor car in a very hilly district when his car stuck on the middle of a hill. Still more unwisely he took an undue share in pushing the car to the top of the hill. He felt that it was an exertion such as he had never put out before in his life, and wished that his car were lighter. When he got to the top of the hill there was nothing for it but to lie down; and from that day for several weeks he was on his back seriously ill. When I saw him some months later he had recovered, and his heart was perfectly normal; but the history of the case suggests, I think, that he did seriously and acutely dilate a normal ventricle.

So with regard to traumatism of the heart, you will recognize that the difference between the cases in this third group and the cases in the former groups is that these latter patients survive the injury, which is some sort of fierce strain, and have time to suffer from symptoms of actual cardiac disease. Please recognize that there are two forms of injury in this class of case, laceration of a valve and great distension of a cavity, and that there are two classes in which these injuries occur, one with antecedent disease and one without antecedent disease.

One of the difficulties of a clear appreciation of the frequency with which the rupture of a healthy valve occurs is due to the fact that if the patient survives the accident for even a few weeks, when death ensues chronic inflammatory changes will have taken place in the valve even though before the rupture it was perfectly healthy.

Another difficulty in establishing, even by pathological evidence, the existence of traumatic heart disease, is due to this fact: that rupture of a diseased valve—perhaps I had better not say rupture—detachment, or separation of a diseased valve may take place as the result of ulceration apart from any severer strain than is naturally taking place in every heart in which blood is circulating.

II.—PROFESSIONAL DIFFICULTIES IN RELATION TO ACCIDENT INSURANCE.

I now come to the second part of my lecture, and propose to speak to you of some of the professional troubles which are connected with this increasing tendency of the community to insure against the result of accidents. I would have you recognize that this habit is putting upon the profession a totally new class of work—a class of work for which no courses of instruction have been laid down, to which no compulsory lectures are assigned, and which, as far as I know, is not dealt with in any of your too numerous examinations.

Let us look for a moment at what are the existing branches of professional work. First of all, there is our duty to seek out the causes of disease and methods of alleviation and prevention. That is the branch of work which is always being carried on by the medical scientist, whether he be a mere physician striving in his laboratory—which is his ward—or whether he be a special pathologist working under more fortunate circumstances, with proper assistance in his endowed laboratory. The second branch of our work is that of endeavouring to persuade a reluctant public to put into effect the methods of prevention of disease which we have discovered. This falls to the lot of the medical officer of health. The third function of the profession, and hitherto the last, is to cure the patient. This is the duty of the great body of the profession, be they general practitioners or consultants. But now we have a fourth duty, a totally new duty, put upon us. This is, to hold the balance even between conflicting pecuniary interests, the just settlement of which can only be determined by medical knowledge. It is a thing we have not bargained for, and a thing that we are not at present very skilful at performing. It becomes our duty to decide, for example, when a man is insured against the results of accidents and becomes ill, whether it is fair or unfair for him to receive the benefits of his insurance. The

difficulty of deciding this, I think, may already have been made clear to you from the cases which I have related of traumatic heart diseases. Let me give you a few other illustrative cases which have recently come under my notice.

CASE V.

A butler, fully insured by his master against the results of accidents occurring in his occupation, is endeavouring to perform his special duty for his master of uncorking for him a special bottle of port. Very anxious not to break the cork—I think that is the right expression—but finding the cork extraordinarily tight, he put out great force, and just as the cork came out he felt a severe pain in his right iliac fossa. Within a day or two he was operated upon for gangrenous appendicitis.

Is that a case in which it is fair for the insurance company to have to pay the insurance money? Is that a case in which it is fair for the employer to be deprived of the advantages of having insured his servant against the results of "accidents"?

CASE VI.

A labourer was digging on a plot of land. It was 5 o'clock on a winter afternoon. His work was over. He walked home, had his tea, and, while sitting down after tea, suddenly had a violent pain in his head, and in twenty-four hours was dead from cerebral haemorrhage.

Was that an accident resulting from the heavy strain of digging in the ground? Is it fair that the insurance company should pay for the death of this man, or is it fair that this man's dependants should be deprived of the advantages of his insurance?

CASE VII.

A factory hand was taking part, as he often did, in moving a piece of iron. He felt a pain in his back, but took no notice of it, and went on moving other pieces of iron. He was not quite so well the next day, but went to work. The following day he had pins and needles in his toes, and in three days was lying in a London hospital with all the symptoms of acute myelitis.

CASE VIII.

A gardener was walking along, pushing a mowing machine in front of him. He suddenly stumbled, and, in trying to save himself, "ricked his back." From that day forth he was a wreck from neurasthenia. He thought he had all sorts of diseases and pains everywhere. There could be no doubt that he had neurasthenia.

Was the neurasthenia the result of the accident? Was it not rather the result of the fact that the law provides that his master shall compensate him for illness produced by accidents?

CASE IX.

A hunting man had influenza. He was recovering from it, and his wife entreated him "not to hunt to-day." He did hunt that day, and when so doing was thrown, soon scrambled up again, went on, and finished the run. Next day he was not so well. The day after he had a rigor, and in three days he was dead of acute pneumonia.

Was his acute pneumonia the result of accident? Was it fair that the insurance company, restricting its policy to the direct results of accidents, should have to pay?

Now, gentlemen, why I ask you carefully to consider this question is because it seems to me to be likely that if this work of deciding these pecuniary interests is carried on as it is carried on at present, it must lead to a degradation of the profession in the eyes of the public.

A lay authority in the insurance world frequently consults me on such subjects as I put before you to-day. He says, "Do you think that such and such a condition was due to the accident?" "No, I certainly do not." "Do you think any medical man of repute can be found to go into the witness-box and say that he thinks it was the result of the accident?" "Yes," I say; and he shrugs his shoulders with an expression which shows what he thinks of the medical profession. But he does not understand the position. He does not know how difficult it is for us; how impossible sometimes to estimate which of the numerous possible causes of any disease is the dominant one in an individual case. He is accustomed to legal decisions which are made upon authority, and not to medical decisions, which are often necessarily indefinite. My friend thinks when he extracts from me the fact that other members of the profession will swear to an opinion different to that which I have expressed, that this is an indication of the fact that the members of the medical profession will accommodate their opinions for the purpose of sale. Of

course there are black sheep in every fold. But the striking differences of opinion that may be held by honourable men are inherent to the nature of the cases. Nevertheless, the fact that it is constantly happening, that one medical man is giving evidence on one side, and another man is giving directly opposed evidence on the other side, is in my opinion having a very deleterious effect upon the high regard in which the profession is held. Not only so; the present method of settling these cases is causing a most unnecessary expense to the community.

REMEDIES.

Now let us consider possible methods of reforming this uncomfortable position for the profession. The first one I should like to urge upon you is this, that we, as members of the profession, should insist that in this matter we will be arbitrators and not advocates. I have the highest possible respect for the legal profession, and am certain that it is in every particular as honourable a profession as that of medicine; but I am convinced of the fact that the unfortunate necessity which compels members of the legal profession to act as advocates, and to defend people against charges which they know to be true does, in the eyes of an unscrupulous public, somewhat lower the esteem of the profession generally. We do not want to be advocates. We, as a medical profession, if we are called upon to perform this new function of seeing fair play between different pecuniary interests, should take the position if we can of arbitrators and not advocates.

It should not be impossible to set up a special tribunal to deal with these questions in which independent medical men with special experience should act in a judicial capacity as arbitrators or assessors to a legal arbitrator. Before such a tribunal, medical evidence should be restricted to questions of fact observed by medical men actually in charge of the patient.

But there is another means whereby we might possibly lessen the complexity of the problem to be arbitrated upon in many cases. The problem in most cases now is how far has the traumatic element anything to do with the condition? Cannot we persuade the insurance companies; cannot we persuade the Government; cannot we persuade the people generally, that while they are about it, insuring against the result of accident, they should, instead, insure against invalidity of all sorts? It is not often, though no doubt it is sometimes, a difficult thing for a medical man to say definitely that this man has a disease and that man has not a disease, but it is constantly a very difficult thing to say whether the disease from which any man is suffering, or has died, is due to a specific cause or not. If the hunter, for instance, is insured against death and not against death from accident, it does not require extraordinary skill on the part of a medical man to certify that he is dead—a duty, by the way, which under existing circumstances is imposed upon us by the State without remuneration.

That insurance against invalidity from all causes is much needed in the case of nearly all breadwinners none can doubt. If the medical profession in a desire to deprive itself of unnecessary work helps forward this movement, its action will be entirely in keeping with its best traditions. We are always working hard to add the whole profession to the ranks of the unemployed.

There is another professional difficulty raised by this habit of insurance which is deserving of your careful attention. It seems right that we should recognize that as a profession our pecuniary relations are necessarily somewhat different to persons who are insured to those who are not.

In the days before insurance became common any breadwinner who met with a serious accident which incapacitated him was at once in the eyes of the profession probably a suitable subject for charity, and his presence in a hospital passed without question. But when the breadwinner is definitely insured against the results of his accident, or can claim compensation covered by insurance, it becomes a very doubtful question whether the medical profession should give their services without payment in order to save the insurance companies from the responsibility of paying their agreed liabilities.

This is, however, a complicated subject on which I have not time to enter now, except to say that, like the other professional difficulties to which I have already referred,

it can only be wisely dealt with after prolonged discussion and careful action.

And now one or two words as to what steps you individually can take in order to meet these difficulties. I want you to appreciate that no amount of the highest possible individual professional uprightness will really enable you to do much in meeting these and many other difficulties which are assailing, or are likely in the near future to assail, the profession.

The recently issued report of the Poor Law Commission indicates the possibility of social changes which may profoundly alter the relations of the profession to the State.

All our professional difficulties become less the more careful we are that each of us shall always be actuated by the highest professional motive, that is to say, that in all our dealings we shall have an absolutely single eye to the advantage of the patient and no regard whatever to our own personal interests. But this will not enable us entirely to meet the collective difficulties of the profession.

It can only be by concerted action of the profession as a whole that such modifications in procedure as I have been suggesting can be carried out. You are doing your little part at present; you are paying fees to universities and to examining bodies to whom you may look in the future, perhaps, for some help in organizing the affairs of the profession. Later on you will pay a fee to the Registrar of the General Medical Council, and you may then look to the General Medical Council, perhaps, to secure such reforms as the future may make necessary. But I think that after some experience you will have to admit that neither the universities, the examining bodies, nor the General Medical Council can do much for you, because even if they had time to spare from their special duties, they have no recognized means of determining what are the wishes of the profession. As soon as you are qualified it becomes your duty to enrol yourself as a member of some of the many societies which are formed amongst medical men in order that they may together discuss concerted action to enable the profession in the most effective way to carry out its high mission and to maintain its worthy reputation.

And here may I suggest that of the various societies that you will have the opportunity of joining, perhaps the British Medical Association is one most deserving of your attention, from the fact that whereas while taking part in the local work—social, scientific, and political—of your own Division, you will, through the central organization, be brought into contact with Divisions all over the British Empire. If you recognize the limitation of your individual effort you will appreciate the great advantage of belonging to a body which is in touch with your professional colleagues all over the world.

You will be told by some, perhaps, that you will find in the Association a narrow spirit of trade-unionism. On the contrary, I believe you will recognize in it, as I have certainly done, the high ideals of a professional guild endeavouring to maintain in each of its members the best professional traditions.

Join the British Medical Association in the same spirit as many of you are now joining the officers' training corps of the Territorial Army, not for what you can get out of it, but for the opportunities it will give you of serving your profession, and, through your profession, the public. Be actuated by the motto of the hospital, "Dare quam accipere."

AN open-air school for tuberculous children has been established on an old ferry boat which was recently turned into a day camp for tuberculous patients by Bellevue Hospital, New York. The school is maintained by the Board of Education, and at present there are thirty-five pupils in attendance, ranging in age from 6 to 15 years. The children are carefully protected from the cold, and work at their desks in all kinds of weather. The school hours are short, as the main object is to make the children well. A record is kept every day of the weight and temperature of the children, and milk and eggs are given to them at odd intervals. The improvement in some of the children has, according to the *New York Medical Journal*, from which the account of the school is taken, been remarkably rapid.

A Clinical Lecture

ON

THE TREATMENT OF A CASE OF EXTENSIVE INFANTILE PARALYSIS BY OPERATION AND APPARATUS.

DELIVERED AT GUY'S HOSPITAL,

BY R. P. ROWLANDS, M.S., F.R.C.S.,

ASSISTANT SURGEON AND SURGEON IN CHARGE OF THE ORTHOPAEDIC
DEPARTMENT.

The prevalent treatment of infantile paralysis is not always satisfactory, for several reasons. It calls for a great deal of care extending over a long time. Deformities develop so insidiously that they may appear to be inevitable, whereas they are mostly preventable. The value and importance of suitable instruments designed to prevent these contractures are not sufficiently recognized, and there is a current idea that instruments of all kinds do not aid but hinder the restoration of function. The advantages of well-planned exercises are little understood, whereas much faith is placed in comparatively useless massage and electricity. The parents expect quick results, get tired of tedious methods and discontinue them. The value of timely operations designed for the restoration of the balance of power around joints and for the firm support and equilibrium of the body is not yet thoroughly appreciated.

It is, therefore, common to see patients at hospitals and in the street whose condition could have been much improved by rational treatment at an earlier date. Too often surgical aid is not sought until such grave deformities have developed that ideal results are impossible. In a few cases the permanent paralysis is so extensive that all treatment seems to be useless. The following account may help to show that something may be done even for some of these apparently hopeless cases.

A girl, aged 17, was referred to me at the orthopaedic department, Guy's Hospital, by Dr. Spurgin, who had recently taken an interest in the patient, but had never attended her.

History.

On August 6th, 1894, when the child was only 3 years old, she had a chill, and cried a good deal during the night. In the morning both her legs were found to be completely paralysed. For two or three days she had retention of urine, relieved by a catheter. There were no other children struck with paralysis at the time, either in the house or neighbourhood. Rubbing and electricity were tried at various times without any appreciable effect, but time gradually brought a little return of power of moving the hip joints. No instruments or splints were ever used.

Condition on Admission.

When I first saw the patient, in October, 1908, her condition was pitiable, her lower limbs being paralysed and terribly deformed. (See Fig. 1.)

Both knees and hips were flexed and the lumbar spine was arched. It was impossible to get the legs any straighter

than is shown in the figure, without increasing the lordosis of the lumbar spine.

Standing and walking were impossible, but the patient could shuffle along by grasping and moving her feet with her hands (Figs. 2 and 3). Consequently the arms were remarkably well developed. Both lower limbs were greatly withered and abnormally short. Their circulation was poor, the pulse being small, and the feet and legs were mottled blue and cold.

The paralysis appeared to be complete below the waist except for the power of:

1. Very weak extension and abduction of the right hip.
2. Weak flexion and adduction, with very weak abduction and extension of the left hip.
3. The peroneus tertius and the flexors of the toes on the right contracted a little, and the calf muscles on the left were not completely paralysed.

Both ankles were flail, and when the patient crawled about they assumed the valgus position. The hips were not dislocated but were firm. The reflexes were abolished in both legs, but sensation was not impaired. The bladder and rectum acted naturally and menstruation was normal.

Treatment.

On October 29th, 1908, under general anaesthesia the following procedures were carried out on both sides at one sitting lasting nearly an hour. The right limb being the

most contracted was dealt with first. The femoral artery was felt pulsating just below Poupart's ligament, and the left index finger was constantly kept over the anterior crural nerve, and

Fig. 1.—Showing the patient lying down. The flexion of the hips and knees and the lordosis of the lumbar spine are shown.

Fig. 3.—Showing the mode of progression and the permanency of the lordosis.

external to the artery, as a guide to prevent any injury of the main artery or of the nerve by the tenotome, which was never passed as far in as the finger. A curved, long tenotome was introduced about 1 in. below and outside the anterior superior spine between the skin and the contracted anterior structures, which were gradually divided, while an assistant pressed the knee backwards. Similarly, through the same puncture, the blade was passed backwards towards the buttock, and the shortened fasciae and abductors were severed while the knee was pressed inwards. In spite of vigorous manipulations it was not possible to straighten the hip until the anterior tissues had been divided down to the very neck of the femur. The external finger held outside the large vessels and nerves was of considerable value during this operation. The knife was not removed until the thigh was extended to the full degree, and remained in this position when all pressure was removed from the lower end of the femur. Remarkably little bleeding into the tissues followed the extensive cutting that was necessary.

A tourniquet was applied around the middle of the thigh, which was protected with lint. The shortened tendons behind the right knee were divided simultaneously, care being taken to avoid injuring the external popliteal nerve. It was not thought necessary to divide any tendons behind the left knee.

The knee-joint was opened through a curved incision passing across the ligamentum patellae, which was divided. Half an inch of the lower end of the femur was sawn off, and a quarter of an inch of the upper end of the tibia, but this did not allow the knee to be straightened. Consequently more bone had to be removed from the femur. The last section was just below the adductor tubercle and the epiphysal line. Thus each limb had to be shortened about $1\frac{1}{2}$ in. before it could be straightened without exerting too much tension upon the contracted popliteal vessels and nerves.

The high section of the femur had the advantage that it left a raw surface only a little larger than that of the tibia. Usually the bones do not fit so well. The experience gained from the right knee was valuable when dealing with the left. The necessary amount of bone was removed without delay upon experimental sections, and thus time was saved.

So much bone had to be removed that it was no use sewing the upper half of the patella to the front of the tibia with the idea of preventing flexion. Therefore the kneecap and a good deal of pendulous skin was removed and the wound closed.

A sealed dressing was applied to the punctures upon the hips. Antiseptic gauze and wool were bound round the knees, and the tourniquets were removed. Perforated tin splints were incorporated in the dressings to stiffen the knees, and the patient

at once fixed in a double Bryant splint without extension. Very little shock followed the operation, and the wounds healed perfectly, but there was a good deal of pain in the right leg, due to temporary obstruction of its circulation and stretching of the popliteal nerves. The foot became blue and insensitive, and the pulsation of the posterior, tibial, and dorsalis pedis stopped.

These symptoms were relieved by allowing the knee to bend a little for a few days, and by removing a constricting gauze bandage which, having been applied wet, had contracted in drying. The circulation and sensation soon returned, but some of the epidermis peeled off.

Twelve days after the operation the knees were fixed in Bavarian plaster splints, and the double Bryant splint discontinued. The hips were extended daily to prevent contractures. Three weeks after the operation the patient was able to flex both thighs a little, and she tried to move the hip in all directions.

The apparatus shown in the photograph (Fig. 4) was applied five weeks after the operation, and the patient was instructed and helped to learn diligently the arts of balancing, standing, and walking. Gradually she became more and more proficient, and quite used to her instrument. She was very pleased with

the exalted position of her head, and much impressed by the increased range and different point of view.

She went out well satisfied on January 5th, 1909, nine weeks after the operation. The knees were firmly united, and all the movements of the hip were increasing. She could flex both thighs about twenty degrees, so that she could walk on the level with the aid of a little support from crutches. She could stand alone without these, and she will slowly be able to dispense with them for walking. (See Fig. 4.)

DIAGNOSIS.

The rapid onset of the disease during early childhood, the extent of the paralysis and its irregular and capricious distribution, are characteristic of acute anterior poliomyelitis, but the persistence of such complete paralysis and the temporary loss of power of the bladder are unusual features.

That the lesion is one affecting the lower neuron is clear from the extreme wasting and want of growth of the legs, the reaction of degeneration and the abolition of the reflexes.

The extent of the paralysis points strongly to the lumbar cord as the site of the disease, and the absence of anaesthesia shows that it did not extend into the posterior columns. Therefore, transverse myelitis and other affections of the lumbar enlargement of the cord are excluded. Peripheral neuritis does not lead to such a lasting paralysis, nor does it select the motor and leave the sensory fibres unaffected. No primary disease of muscle develops so suddenly, nor do any of them have the same distribution as in this case. Therefore the diagnosis was easy, and nearly all the interest of the case is centred in the treatment. But please remember that rational treatment depends on accurate diagnosis; and that in these cases the diagnosis is not completed until you can tell which muscles are affected, or, as in such an extensive case as this, which muscles or movements have not been completely paralysed or abolished. About the hips it is not easy to tell which muscles are damaged, but lower down it is fairly easy.

In any case, movements are more important than muscles. You may remember

that my patient had practically no muscular power below the hips, and that only the feeblest movements of those joints were possible. These facts were of great value in deciding upon the treatment. When the natural relations and the normal range of movements of a joint are restored, any weak muscles acting upon the joint are capable of increasing growth and power.

It was of supreme importance to ascertain that the heads of femora were firmly articulated in the acetabula, for if the hip-joints had been dislocated or unstable, the value of the ilio-femoral ligament would have been reduced to a minimum, so that balancing and standing would have been difficult or impossible without lessening the mobility of the hip-joints.

TREATMENT.

With deformities, as with other evils, prevention is better than cure. Much can be done to prevent contractures even in extreme cases of infantile paralysis. It is very desirable to do this whenever possible, because the deformities are not only bad in themselves, but they also

Fig. 4.—Showing the patient wearing the apparatus after operation.

interfere with the nutrition and development of any muscles that may have escaped complete paralysis. The stretching of weak muscles and the contracture of their stronger antagonists lead to progressive wasting of both, because a free range of movement is essential to the healthy circulation and growth of all muscles.

It is obvious that the actions of muscles must be imperfect when the joints and bones upon which they act have lost their natural mobility and shape.

It is of vital importance, therefore, to prevent contractures, and incidentally to avoid the need of operations whenever possible. A good deal can be done by:

1. Regular and vigorous stretching of the muscles, which tend to retract.

2. Developing their antagonists as far as possible by active and passive movements, massage, and electrical stimulation.

3. And lastly, by the use of suitable instruments, especially at night.

For instance, in this patient, contractures of the knees and hips could have been minimized by passive extension of these joints several times daily, by encouraging voluntary contraction of the extensors, and especially by the use of a double Thomas's hip splint at night. Then an apparatus, such as she now wears, could have been used in the day, without any need for a preliminary operation. In these ways the mobility of the knees and the normal stature could have been preserved.

It is interesting that the patient herself unconsciously prevented the development of talipes equinus by putting her weight upon her feet during her endeavours at progression.

OPERATION.

After carefully examining this patient and realizing the extreme severity of the contractures and the extent of the paralysis, I was inclined to advise against operation. But the patient, who had come all the way from Newcastle, was very anxious to have something done even at a considerable risk. Above all, her plucky endeavours to move about induced me to change my mind. The girl was so keen to help herself, that it seemed worth while to give her a sporting chance of learning to stand and walk with the aid of instruments. I did not dare hope that the result would be so good as it has already become in the short time that has elapsed since the operation. I have been greatly surprised to watch the development of so much power of moving the hip-joints. The most I expected was progression by rotary pelvic movements, but there is now no need of this ugly method, for the patient can flex the hips sufficiently to enable her to walk. These are some of the points which make me consider this patient a good subject for my clinical lecture.

Division of Contracted Tendons and Fasciae.

It was evident that these procedures would be insufficient to overcome the extreme contractures which had taken years to mature in this patient.

The vessels and nerves were also so greatly shortened that the simultaneous straightening of the hip and knee would throw an excessive strain upon these vital structures, which were unusually small in these withered limbs. The hips could have been first extended, and then the knee straightened after an interval of some weeks, during which the vessels and other structures behind the knees could be gradually stretched.

In this way slighter contractures of the knee and hip can be corrected without excising the knees and shortening the stature; but in my patient this method did not appear hopeful, on account of the degree and rigidity of the contractures and the withered condition of the limbs. Moreover, the bony and articular changes at the knees from long malposition and the total absence of muscular power made it certain that the knees could not be brought quite straight. In any case they would be frail.

The initial cost and ultimate expense of an instrument under these circumstances would be much greater, which is an important point for poor people.

Arthrodesis was unsuitable because the knees could not be extended without free removal of bone, and the union is not so likely to be firm as after excision. I therefore decided to undertake a more radical operation which could be completed at one sitting. I have generally dissected away the shortened fasciae for severe contractures of the

hip to lessen the risk of recurrence, but in this patient, in order to save time, I was content with subcutaneous but very free division. Recurrence of the contracture can be prevented by passive movements and instruments. When the hip was fully extended the tension of the hamstring was somewhat relieved, so that the flexion of the knee was diminished to some extent. Tenotomies, however, made but little difference, and a very free excision of bone was necessary.

Instruments.

The day instrument and a posterior night splint prevented bending of the knee at the union and at the epiphyseal lines.

The apparatus shown in the photograph (Fig. 4) is provided with toe-lifting springs and T valgus straps. There are no joints at the knees, which are kept firmly fixed by straps. The side-irons take some of the weight off the legs, and the whole apparatus, including the pelvic girdle, adds to the stability of the body.

For making the instruments I am much indebted to Mr. Pengeley, of Catherine Street, Strand. My best thanks are also due to Mr. Perkins, my late House-Surgeon, and to my dressers, for their help during the operation and after-treatment.

THE NERVE SHEATH IN THE CAUSATION AND TREATMENT OF NEURALGIA.

BY ROBERT M. SIMON, M.D., F.R.C.P.

PHYSICIAN TO THE GENERAL HOSPITAL, BIRMINGHAM.

THE influence of pressure as the cause of neuralgia, especially in the case of the branches of the brachial and sciatic nerves, is so abundantly recognized, that it seems unnecessary to labour or illustrate the point. It is not, however, sufficiently recognized that this pressure upon the sensory elements of the nerves may arise, not only from causes entirely outside the nerve bundles, but also from changes in the perineurium, that is, the nerve sheath.

These changes may be due, firstly, to an extension of inflammation from surrounding tissues, as in the cases of brachial neuralgia, in which one can frequently, in my experience generally, elicit a history of bruising of the muscles or fibrous tissues surrounding the nerves; secondly, to such toxic conditions of the blood as have a tendency to cause proliferation of the connective tissue in the immediate neighbourhood of blood vessels, for example, chronic alcoholism; and thirdly, to acute congestions of blood vessels in the sheath of the nerves. This form of neuralgia is apt to occur in influenza, or as an after effect.

Morphologically, there is, I am told, no such thing as a nerve sheath—that is, no separate structure which can be clearly defined and exhibited; but, while this is no doubt true, and nerve elements cannot be found lying loose in a nerve sheath as a nut in its shell, it is true enough for all practical purposes that there is a distinct nerve sheath. The connective tissue which forms a nerve sheath is continuous externally with the connective tissue outside it, and from its inner surface fine trabeculae of connective tissue extend to form a protective covering between and round the myelin and axis cylinders of the nerve elements. Blood vessels are carried in all these connective tissue structures, and it is, I believe, upon the congestion of these vessels that the occurrence of pain depends. There is no lymph space between the sheath and the nerve elements proper, and for this reason any material overfullness of the vessels of the sheath, or a very slight oedema around them, or exudation into the lymph spaces in the interstices of the sheath will of necessity cause an amount of pain altogether out of proportion to the pain which would be caused by an equal or vastly greater effusion outside and round the nerve sheath itself.

If this theory of the cause of pain is correct, the failure of many methods of treatment in some cases of sciatica and brachial neuralgia will be explained and the reason for the success of other methods rendered probable.

To some of these methods I will revert later, but will now give details of two cases that seem to illustrate the truth of the proposition that it is often the condition of

things inside and not outside the nerve sheath that is the cause of pain.

CASE I.

J. W. O., a miner, aged 32, was admitted to the General Hospital in Birmingham under my care on February 29th, 1908, complaining of sciatica.

In March, 1907, he had a good deal of pain in the left buttock; this gradually got worse and extended down the leg. It soon became so severe that he had to give up work, and, failing relief from medicinal treatment, he went to Droitwich to try brine baths. He improved somewhat, but soon got as bad as ever, and in February when he was admitted to hospital was unable to walk on account of the pain. I am sorry to say I wasted a month of his life in trying to relieve him with drugs and local applications.

As he was unrelieved I asked my colleague, Mr. Barling, to cut down upon the sciatic and open the nerve sheath. This was done on April 1st, and numerous tough red adhesions between the sheath and the nerve were found. These were broken down and the nerve stretched inside the sheath.

Next day he was fairly comfortable, except for some pain due to the incision.

Three days after the operation it was noted that all pain had gone, and that the patient had not enjoyed so long a freedom from pain for months.

Ten days later he was discharged, free from pain, and able to walk with perfect comfort. He has remained quite well since.

CASE II.

A gentleman, aged 65, recovered very slowly from a severe attack of influenza.

During his convalescence I was asked to see him again on account of intolerable pain down the arm, and especially in the distribution of the musculo-spiral nerve. This pain was most marked about the middle of the upper arm, where the nerve is most superficial, and was associated with exquisite tenderness. No drug treatment made the slightest difference to him, except large doses of antifebrin, which gave him moderate, if transitory, relief. Radiant heat gave more freedom from pain than anything else. Leeches, blisters, and all sorts of local applications were tried, but ineffectually.

Very slowly and gradually the pain lessened, but never entirely left him, until one day it suddenly became worse than ever, and the temperature, which had been normal, began to vary from 99 to 100.5. I told him that there was probably inflammation inside the nerve sheath, and urged operation, thinking that there might be adhesions also between the nerve and the periosteum.

He would not entertain the idea, but after a week of misery consented to anything being done.

Mr. Barling cut down on the musculo-spiral nerve at the point of maximum pain, and found it adherent to the periosteum. The adhesions were broken down and the nerve sheath opened.

The same treatment as in the case of sciatica was adopted. Immediate relief from pain followed, and tenderness gradually disappeared.

It seemed certain that no other treatment would have been so immediately useful in either of these two cases; indeed, no other treatment had done more than give temporary relief.

Nerve stretching, from which so much was expected in the treatment of severe long-standing cases of neuralgia, has been abandoned on account of the disappointing results; and, indeed, it is not easy to imagine how any amount of pulling a nerve could influence the inflammatory condition of the inside of the sheath.

It is in the hope that this method of treatment may be criticized that this paper is being published. Of the success of the procedure there can, I think, be no doubt, so far as the relief of pain is concerned. I would only urge that it should be adopted before trophic changes occur, as Dr. Fleming, of Edinburgh, and others have pointed out that, even if a nerve is healthy to begin with, continued pressure will ultimately end in disorganization of the axis cylinder and the production of trophic troubles.

In the *Practitioner* of 1886 the late Sir Joseph Fayrer published a case in which what was believed to be a swelling of the nerve sheath was opened and about a couple of drachms of clear fluid evacuated, with immediate relief to the severe sciatic pain which had been complained of. I have had an equally good result in a case of severe neuralgia of the ulnar nerve in which a similar course was adopted.

Many instances of the cure of sciatica by acupuncture have been recorded, due doubtless to the setting free of fluid accumulated between the nerve sheath and the myelin of the nerve; but though this method may be, and often is, successful, it cannot compare, any more than can the procedure adopted by Sir Joseph Fayrer, with the more thorough operation of cutting down on and opening the nerve sheath and the separation of internal adhesions.

AURAL VERTIGO.*

By W. S. SYME, M.D. EDIN.,

ASSISTANT SURGEON, EAR, NOSE, AND THROAT HOSPITAL, GLASGOW.

SINCE Ménière's description in 1861 of a case of the disease with which his name has been since associated, this title has been extended to include a variety of cases bearing more or less resemblance clinically to that properly called Ménière's disease. Yet, viewed from the pathological standpoint, the great majority of these have no right to be thus included, and, on the other hand, there are other cases in which similar changes have taken place in the ear, and which, nevertheless, have been considered quite distinct and unassociated with aural disease. Some authors have attempted a compromise by limiting the name to the rare variety first described and grouping the others under the title "vertigo with aural lesions and Ménière's symptoms," obviously a makeshift, but probably as good as was possible owing to the limited knowledge of the actual pathological changes in the ear, and especially in the labyrinth.

DEFINITION.

The result of the researches of many observers, both in this and other countries, during the past few years on the changes in the middle and internal ears consequent on disease, suggests the advisability of a thorough overhauling of our terminology. Indeed, the application of the name of any man, however distinguished, to a disease cannot be regarded as scientific, and is, in fact, likely to hamper the study of its details. There is no doubt that this has been the case with reference to the subject of this communication. In aural disease, as in disease of other parts, the only scientific nomenclature is that based on pathological findings, and in this way only can cases be relegated to their proper category. So that, as Lermoyez remarks, the time has come when the name "Ménière's disease" should be abandoned and our nosology revised in the light of the conditions found *post mortem*. For the present, however, we may retain the title to denote the condition actually described by the original observer.

As a matter of fact this is a very rare disease, an observation which, I have no doubt, will occasion surprise in view of the frequency with which the name is used. The case described by Ménière before the French Academy of Medicine was that of a young woman who during her menstrual period was suddenly and without evident cause affected with deafness, accompanied by vomiting and severe vertigo. Five days later she died, and on *post-mortem* examination the only lesion found was hæmorrhage into the semicircular canals, and to a less extent into the vestibule, while the cochlea was not affected. (It may be remarked here that a fatal issue to Ménière's disease is unusual.) Cases presenting the same clinical symptoms had previously been reported, but they were considered to be due to hepatic, stomacic, renal, cerebral, cerebellar, or other cause, and their connexion with an aural lesion was not suspected. From this case Ménière concluded that these previously reported cases, and others resembling them in showing the symptoms of sudden deafness, loud subjective noises, severe vertigo—the three cardinal symptoms as they have been called—taken in connexion with the well-known results of experiments on animals, were due to hæmorrhage or acute inflammatory exudation into the semicircular canals. Unfortunately, as I have said, the generic term "Ménière's disease" has been used to include all cases in which these symptoms have presented themselves, in whatever degree and in whatever manner of appearance. Hence the confusion of thought which has arisen. We may, however, use the parent disease as a guide to describe the various aural conditions which give rise to vertigo.

ANATOMY AND PHYSIOLOGY.

Let me rehearse in little detail the anatomy and physiology of the internal ear, for it will aid us in understanding the phenomenon under consideration. It must be looked upon as a double organ, dealing both, and to a certain extent separately, with the sense of hearing and with the sense of position in space—the static or, better, the spatial sense.

* Read before the Border Counties Branch of the British Medical Association.

The terminal organs of these two senses are delicate membranous structures, comprising together the membranous labyrinth enclosed in firm bony chambers, the osseous labyrinth. Though anatomically connected, the functions of these two main parts of the membranous labyrinth are distinct, and, though the nerves which supply them enter the internal ear together as the auditory nerve, they have distinct and separate central connexions and courses. The cochlea is the organ of hearing, and has its own nerve, the cochlear nerve, while the vestibular nerve, the nerve of the spatial sense, passes to the semicircular canals and the vestibule. The osseous labyrinth has two openings in the wall contiguous to the middle ear, the fenestra rotunda and the fenestra ovalis, the former leading to the cochlea, and closed by the membrane of the round window, and the latter leading to the vestibule and closed by membrane and the footplate of the stapes, the inner termination of the chain of ossicles. The fenestra ovalis is, as we shall see, of importance in reference to the question of vertigo. As regards the position of the canals relative to the tympanic cavity, the horizontal or external canal has the closest relationship, lying immediately beneath the inner wall of the aditus, where during the performance of the radical mastoid operation its external service can be seen separated from the fenestra ovalis by the prominent Fallopian canal containing the facial nerve. The superior canal comes to the surface in the upper part of the inner tympanic wall above the fenestra ovalis. The posterior canal is not contiguous in any part to the middle ear. From its position we are prepared to find that the external canal is the one most liable to be affected by the extension of middle-ear disease. Between the osseous labyrinth and the membranous labyrinth is the perilymph, and inside the latter the endolymph. The perilymph is in communication with the arachnoid cavity. The arterial supply comes from the auditory artery, a branch of the basilar, and the veins empty into the lateral and superior petrosal sinuses. There are, however, communications between the blood vessels of the inner and middle ears through the outer wall of the labyrinth or the inner wall of the tympanum.

The physiology of the internal ear is not by any means clear even yet. We are not at present concerned with the auditory part, though that presents unsolved problems, but in connexion with the spatial portions their exact relation to the maintenance of equilibrium of the body and to the appreciation of motion in different planes is still a matter largely of speculation, while their connexion with ocular movements and, it may be, with muscular tone requires further study. Since the classical experiments of Flourens on pigeons there have been many workers in this field—notably Weber, de Cyon, Loewenberg, Delages, Helmholz, Crum Brown. When, however, we come to details, we find conflicting and contradictory results. Indeed, from the nature of the case this must be so, for, as Hartmann says, it is impossible to determine whether the results are due to stimulation or to depression of the functions of the vestibular nerve. There is, however, practical agreement that the semicircular canals perform an important function in the maintenance of equilibration, and probably we may accept Crum Brown's theory that the canals on either side in their action balance those in similar planes on the other side.

The mode of action of the canals is, as I have said, still the subject of much discussion, and, as with experimentation so with the action of diseased and degenerative processes, it is difficult to decide whether we have to deal with a condition which excites or depresses the peripheral terminations of the vestibular nerve. Looking, however, to the results of destruction of the labyrinth, to the action of pressure on the nerve itself or on its pathway in the brain, and remembering that we are dealing with an efferent nerve, we may say that irritation of the canals leads to a tendency to fall towards that side, or to a sensation as if surrounding objects were moving in that direction, in which case there may be, as Dundas Grant remarks, an involuntary and, as it were, compensatory inclination to fall towards the other side; if only one canal is the seat of irritation, the direction of the vertiginous phenomenon varies with the canal affected. Increased excitability of the canals or of one of them on one side causes the movement of the eyes in that direction which is

translated by the opposing force of the opposite set of muscles into a nystagmus towards the ear involved. On the other hand, the sudden destruction of the canals or of the vestibular nerve on one side leads to deviation of the eyes to the opposite side and to a tendency to fall in that direction. After a time, a few days as a rule, when the destruction is at once complete, the eyes return to their normal position and the body equilibrium also comes again under control. In a case shown before the Otological Section of the Royal Society of Medicine in June, in which the vestibule and canals on both sides had been destroyed some time previously, there was only slight nystagmus and the patient could walk quite straight and with the eyes either open or shut. In deaf-mutes, too, who have afterwards completely or partially lost their sight, as happens sometimes in congenital syphilis, or in blind people who become totally deaf, equilibration is maintained, at any rate to a fair degree. So that de Cyon's contention that the loss of the spatial sense is made good by the sense of vision is not accurate. The patient referred to was, however, quite unable to recognize that she was being rotated when placed on a revolving table, and this fact has also been observed in certain deaf-mutes. In the interesting case of division of the auditory nerve for distressing tinnitus recently reported by Ballance, the deviation of the eyes to the opposite side lasted for only forty-eight hours. We may, therefore, take it that the canals are not essential to normal progression and equilibration though in health they do perform a most important function. The same may be said, though not quite so definitely, with regard to the action of the canals on the eyes, for where the vestibular apparatus on both sides is destroyed, as in the case quoted, or as in certain cases where this has followed disease, a fine nystagmus may remain. The function of the canals with reference to equilibration may be illustrated by the see-saw. When the weight on one end is equal to that on the other, equilibrium is maintained; if the weight on one side, in this case the stimulation of the canals or of the vestibular nerve, is increased, the plank goes down on that side; if the weight on one end be suddenly removed, the plank goes down on the opposite side. In the first case in which Lake destroyed the labyrinth on one side for severe vertigo there was noticed for a short time after the operation a tendency to fall to the opposite side. The direction of the vertigo can sometimes be ascertained only by careful examination. The patient should be instructed to look up, to close the eyes with the feet placed together, to walk along a straight line with the eyes directed forwards or upwards, to jump backwards, to stand on an inclined plane, and to make the examination more thorough the inclination may be varied. The vertigo may only make its appearance on looking quickly towards the diseased side or towards the healthy side if one labyrinth is destroyed. In the same way the direction of the vertigo may be brought out by turning the patient round several times in a revolving chair. In disease I have not found that the direction of the revolution affects the result. Syringing the ear or even the introduction of a speculum may bring on an attack of vertigo. By experimenting on the healthy ear Babiniski found that the positive pole applied to the labyrinth caused a rotation of the head to that side, whereas with the negative pole applied a more violent rotation toward the other side was obtained. No result was got after destruction of the labyrinth nor under chloroform narcosis.

The question of nystagmus is more difficult. Without going into the complex anatomy of the subject, we can state that there are important central connexions between the vestibular nerve and the nerves which supply the muscles concerned in the movements of the eyeballs, and especially with the sixth nerve of the same side. It would appear that the steadiness of the eyes is maintained—in part, at any rate—by the action within normal limits of the canals on both sides. If there is over-stimulation of those on one side, the eyes tend to move in that direction, but by the action of the opposing muscles what would otherwise be a deviation is turned into spasmodic contractions of an intensity varying with the amount of stimulation. In the milder forms the nystagmus only appears when the eyes are turned sharply towards one side or the other, more markedly, as a rule, when turned towards the affected ear, though frequently there is also nystagmus,

less in degree, when the eyes are turned in the opposite direction.

Wittmack and other observers have thought that in the non-suppurative ear affections the nystagmus is usually worse when the eyes are turned towards the healthy side. It is probable that with over-stimulation of the muscles which move the eyes in one direction there is also a reflex increase in the stimulation of the opposing set, so that on both sides we get a condition where complete and normal relaxation does not occur. Experiments seem to show that the direction of the nystagmus depends not only on the side on which the labyrinthine affection is, but also on the plane of the canal chiefly involved, so that we may get a double movement in which the eyes tend to move, say, to the left and downwards, and so on. If sudden destruction of the vestibular apparatus or of its connexion with the brain takes place, we get, as we have seen, strong deviation of the eyes to the opposite side. If the destruction is slow, we may get neither vertigo, nystagmus, nor deviation.

Before leaving this part of the subject, let me say a word about the function of the vestibule with regard to orientation—that is, our knowledge of the position of the body, or, rather, of the head in space. As stated by Horsley, "inclination of the head in any direction is recorded by the corresponding vertical canals according to the plane of movement, and the all-important rotation of the eyes, of the head, and, later, of the whole body, is made known to consciousness by the horizontal canals." Though this function has, of course, a distinct connexion with the maintenance of equilibration, it has primarily to do with our recognition of the position of the head and of the space traversed by it. If we look upon the maintenance of equilibration as the active function of the vestibule, we may consider this the passive. Except as regards the complete destruction of both labyrinths, to which reference has been made, I am not aware that disease of the labyrinth has been studied specially with reference to the knowledge a patient may have relative to various movements.

PAEHOLOGY AND DIAGNOSIS.

Let us now look at this question from the clinical point of view, discussing at the same time the pathological conditions on which it depends, and at the outset let me say that it must be a question of great difficulty in many cases to decide whether we are dealing with a case in which the function of the vestibule is depressed, or is unduly excited by the irritation of early pathological changes, such, for instance, as increased tenderness of an inflamed cutaneous surface. A careful examination of the case in all its bearings must be made, the amount of hearing, the tuning-fork reactions, the appearance of the vertigo with reference to the tinnitus and deafness. Vertigo may be sudden and severe, occurring in a subject previously free from any aural affection. This was the case with Ménière's patient. Such a case is due to traumatism, hæmorrhage, acute inflammatory exudation, or embolism. The severity of the phenomena will depend on the amount of destruction. If the labyrinth is completely destroyed we shall get complete deafness on that side, severe vertigo, tinnitus for a time, vomiting, and, it may be, a period of unconsciousness. In this case, after the vertigo has passed off, we would not expect to get a recurrence. In cases of incomplete destruction, however, though the immediate symptoms are not so severe the patient is liable to have recurring vertiginous attacks. Irregular movements of the eyes occur, and in some cases, as Launois and Chavanne state, there has been noticed facial paralysis, and more rarely paralysis of other cranial nerves. A fatal issue is rare, though it did occur in Ménière's case.

In the large majority of cases of aural vertigo there has been a pre-existing pathological condition of the ears, either of the inner or middle ear, more rarely of the external auditory meatus. This aural condition may have been unrecognized even by the patient, and as we may, and do, of course, have affections of the auditory part of the internal ear leading to deafness, but without any vertigo or giddiness, so it is reasonable to suppose that we may get the static portion affected without any deafness resulting, but giving rise to vertigo or dizziness, whose dependence on an aural affection it would, under the circumstances, be difficult to establish. Careful tests would probably bring out this connexion if it should be sought for; hence there are some who state that all vertiginous

phenomena, except those due to intracranial conditions are dependent on labyrinthine affections; indeed, even Sir William Gowers says that 90 per cent. of the cases of vertigo are due to ear disease. In this connexion it is interesting to note that, *post mortem*, changes have been found in the static portion of the internal ear while the auditory portion has appeared healthy.

As I have said, the trouble in the ear may be in its external, middle, or internal part. The simplest case is that in which a collection of cerumen has given rise to dizziness, or even to vertigo. The cause of this is somewhat difficult to decide. It may be due to increased pressure acting through the membrana tympani, and then through the fenestra ovalis, or the plug of wax may lead to some congestive condition of the labyrinth by the interference with an abnormally free intercommunication between the veins of the internal ear and those of the tympanum and posterior wall of the meatus, or it may be altogether a reflex action. In the same way, water getting into the ear, even with the tympanum intact, has caused vertigo; and it is an interesting speculation whether some cases of drowning may not have been thus caused—a hypothesis far from unlikely when the person has been the subject of middle-ear suppuration. A foreign body—a fly, and so on—may in the same way cause vertigo. The prognosis in these cases is, of course, quite favourable.

Coming now to the middle ear, we may say that all affections of this part may lead to changes in the labyrinth. In the great majority of chronic non-suppurative diseases of the middle ear the internal ear becomes secondarily involved. As a rule, this takes place on both sides so gradually that nothing in the nature of vertigo beyond a very slight feeling of dizziness is complained of. In cases of one-sided middle-ear affection this freedom is not so usual. Moreover, when the protective power of the tympanic membrane and ossicles is weakened, causes which would otherwise do no harm may lead to severe damage to the labyrinth. A loud noise, as the firing of a gun, a band, especially in an enclosed place, and so on, has brought on a vertiginous attack, and the injury in such a case to the canals—it may be congestion, laceration, or hæmorrhage—may be the beginning of recurring and severe vertigo. Apart from these sudden attacks, we do often get vertigo dependent on non-suppurative middle-ear affections. What the actual condition in the canals is it is difficult often to determine. Probably in most there are degenerative changes. Horsley states that we do not get true forced rotation from pure middle-ear disease, but only when the labyrinth or vestibular nerve is involved. In some the attack may be due to increased pressure exerted through the footplate of the stapes. An examination of the hearing by the various tests will in some show that the deafness is definitely of labyrinthine origin. In some, however, the middle-ear affection itself is the cause of the deafness. In many the condition is evidently of a mixed nature. In acute catarrhal and in acute suppurative conditions of the middle ear temporary vertigo is common, but passes off with the improvement in the tympanic disease, though in a certain number the damage to the internal ear is of a permanent character, and may show itself by complete or partial deafness of a labyrinthine character with or without recurring vertigo or dizziness. In children especially we must be on the look-out for an acute labyrinthitis such as described by Voltolini. The attack begins with meningeal symptoms, but consciousness is retained. Deafness comes on quickly, and usually becomes absolute in a day or two. Giddiness is observed if the child sits up, and may be severe. In a few days the attack subsides, but the child remains as a rule permanently deaf, and, depending on its age, deaf-mutism results. I need only mention that secondary changes in the labyrinth occur sometimes in meningitis, basic, tuberculous, or cerebro-spinal. In such cases there frequently remains a fine nystagmus, but vertigo is not a prominent feature.

We now come to a most important question, namely, the relation of vertigo to chronic middle-ear suppuration. Dizziness is by no means an uncommon accompaniment of this affection, and in many cases actual vertigo can be made manifest by the application of various tests, and the same holds with reference to nystagmus. In the great majority of these cases the vertigo is of mild degree, and

is probably dependent on the same conditions which give rise to it in the non suppurative middle-ear affections, that is to say, it and the nystagmus will have the direction got in irritation of the vestibular nerve. At the same time, it is a symptom which deserves very careful attention, and, whether it increases in severity or not, if it is associated with rapid decrease in the hearing and with a loss of bone conduction and of perception for the higher notes it is a danger signal which should not be disregarded. If, in addition, on alterations of pressure within the meatus by the airbag or by a pneumatic speculum, or if on gently syringing the ear an attack of vertigo with or without nausea is caused, then the demand for the performance of the radical mastoid is imperative. If the vertigo should change in type with a tendency to fall towards the opposite side or with a sensation of surrounding objects moving in a direction contrary to that in which they had previously appeared to move, and if the nystagmus should change in direction or if deviation of the eyes to the opposite side should show itself, then one would be right in suspecting the destruction of the labyrinth by the suppurative process. It must be stated, though, that infection of the labyrinth going on to destruction of the membranous contents has been not infrequently found without a history of either vertigo or nystagmus. In such a case the probability is that the membranous labyrinth has been destroyed by a slow inflammatory process in advance of the suppuration. It need hardly be said that it should be our aim to anticipate by operation the spread of the suppurative process to the internal ear with the great risks of intracranial infection which thereby follow. During the performance of the radical mastoid operation the inner wall of the tympanum should be carefully examined for carious points or for a sinus leading into the labyrinth, and this advice applies especially to the region of the external canal and to the oval window. In the great majority of cases, where a timely operation is performed, nothing will be found to make it necessary to open into the internal ear, and the symptoms will slowly subside after the middle-ear cavities have been efficiently dealt with. Such a case, however, should be carefully watched.

Now we come to a question of differential diagnosis. It is a matter of much difficulty at times to determine whether we have to deal with a suppurative labyrinthitis or with an intracranial complication, especially with a cerebellar abscess, in which not unusually the route of infection is via the internal ear. The difficulty is increased in that the cerebellar abscess may be situated in the middle or lateral lobe, or even, as rare cases have shown, in the lateral lobe of the opposite side. It has been said that one is more likely to find a cerebellar abscess at a distance from the primary infection than is the case with cerebral abscess. By far the most usual, however, is an abscess in the lateral lobe of the side on which the ear disease is. Moreover, in the early stage, at any rate, and before complete destruction of that lobe takes place, the lesion, as regards the vestibular nerve, is an irritative one, and, as Horsley and Ballance have shown in the case of extra-cerebellar tumours, and Stewart and Holmes from experiments, an irritation of the vestibular nerve in its course or in its cerebellar connexions leads to a tendency to fall to that side, as is the case with irritation of the labyrinth; whereas in labyrinthine destruction, as by suppuration, the vertigo is in the other direction. At the same time, it must be remarked that, as a rule, cerebellar abscesses are not seen in the early stage, and in reported cases the direction of the vertigo is rarely remarked. Macewen states that vertigo occurs in the early stage of cerebellar abscess, but he also remarks that there are few localizing symptoms at this period. In one of his cases, a child of 3 in whom the right internal ear was destroyed by suppuration, and in whom ultimately a superficial abscess was found in the roof of the fourth ventricle, with also thickening of the dura over the right side of the cerebellum, there was a tendency to fall to the right side when being sat up in bed by the nurse. Macewen Smith states that intracranial complications of aural suppuration, such as thrombo-phlebitis of the lateral sinus and extra-dural abscess, may cause vertigo towards the diseased side. With reference to nystagmus in cerebellar abscess, Whitehead observed in a case successfully treated by operation that this symptom was obtained on extreme

rotation of the eyes to the side of the disease. An adaptation of Barany's test may prove of help in differential diagnosis. He found that cold water poured into the ear is followed by a tendency to fall towards the other side, and that water above the temperature of the body has the opposite effect. Nystagmus, too, in similar direction is caused. If the labyrinth on one side is destroyed, cold water poured into that ear will have no effect in producing vertigo towards the opposite side or in controlling or overcoming a vertigo in the direction of the diseased ear which may be present, nor will nystagmus result or a present nystagmus be affected. I have frequently used Barany's test in patients, and in those in whom the tympanic membranes have been destroyed by disease, so that the fluid could get into contact with the inner tympanic wall on both sides, the results have confirmed his claims; in patients with intact membranes the results in my hands have been inconclusive. In differential diagnosis this test will give valuable help.

Apart from intracranial affections, and especially cerebellar abscess, occurring as complications of middle-ear suppuration, we shall sometimes have to decide between the possible aural or intracranial origin of vertigo where there is no suppuration. The case may be one of cerebellar tumour causing irritation or destruction of one of the lobes of the cerebellum or of the vestibular nerve. Again, the condition may be really of the nature of epilepsy, or we may have to deal with some affection of the nervous system, such as locomotor ataxy or of some general disease, such as Bright's disease or severe anaemia. Ocular defects, too, may give rise to dizziness or vertigo, which, as a rule, disappears on closing the eyes. I have also seen vertigo associated with disease of the sphenoidal sinuses. In all cases of difficulty a diagnosis can be made only after a most thorough examination of all the symptoms; of the eyes for optic neuritis and for the degree of neuritis, of the general muscular system for the presence of paralysis, and, of course, of the ears by the various tests at our disposal. It is so usual to find alterations in hearing and changes in the ears that it must not be concluded from these that the vertigo is necessarily dependent on the aural condition. In few affections is co-operation between the specialist and the physician likely to be more helpful than in this.

COURSE.

As I have before said, if the destruction of the vestibular apparatus is at once complete the first attack of vertigo will be the last. In cases in which the effect on the labyrinth is temporary the vertigo passes off, and the ear may return completely to normal. In many cases, however, a constant dizziness remains, with recurring attacks of severe vertigo, or indeed there may be constant vertigo of such severity that the patient is quite incapacitated from work. There may be accompanying tinnitus and nausea, or these may usher in an attack. In most cases the auditory part of the internal ear is also the seat of pathological changes showing themselves by increasing deafness. Indeed, the only termination that one can hope for in many cases of severe vertigo is complete disorganization of the internal ear when this distressing phenomenon disappears, but complete deafness results. In the recurrences of vertigo it is not always possible to decide on the exciting cause. Certain it is that anything which leads to cerebral congestion may bring on an attack. In cases in which unabsorbed blood pigments or the results of exudation remain in the labyrinth the attack may be referred to a summation of stimuli.

TREATMENT.

As regards treatment, this naturally has reference especially to the underlying aural affection, and in giving a prognosis one has to take into consideration the possibility of the amelioration of this condition, and also the period of association of the deafness and vertigo. In non-suppurative affections of the middle ear in which the vertigo has shown itself much later than the deafness or tinnitus, it has seemed to me that the treatment of the aural condition was more likely to lead to its improvement or disappearance. In treating the symptom itself the drug of most efficacy is quinine. Charcot instituted this treatment on the principle that it gradually destroyed the hearing, when, as we have seen, the vertigo disappears. On the other hand, Urban Pritchard reports a case of severe

vertigo from a poisonous dose of quinine. It is, however, not necessary to give it in such large doses. Given a grain at a time, it seems to reduce the irritation of the vestibular nerve, probably by overcoming congestive changes. On the ground that vertigo is due to anaemia of the labyrinth, which, however, is probably not as a rule well founded, Lermoyez suggested the use of amyl nitrite. We are all aware, of course, that in conditions of severe anaemia vertigo is common, but whether this is an aural phenomenon or not, even when associated, as it often is, with tinnitus, is a doubtful point. At the same time it is quite possible that the actual cause of vertigo is not so much either congestion or anaemia as the alterations in the pressure of the endolymph which may be brought about by either of these states. The bromides and iodides are sometimes useful, and pilocarpine, especially in patients in whom the aural condition is dependent on congenital or tertiary acquired syphilis, has sometimes seemed of value. Repeated lumbar puncture has been used with some, though probably only with temporary, benefit. Patients should be advised to eschew alcohol, tea, coffee, and tobacco, to avoid as far as possible mental excitement and loud noises, and to keep the bowels acting well. During a severe attack the recumbent posture should be enjoined, with ice to the side of the head. When all other measures fail, and when life is made practically intolerable, the advisability of destroying the labyrinth—at any rate the static portion of it—should be entertained. I am referring now to cases of non-suppurative ear diseases. This has been carried out in this country by Milligan, Lake, and Yearsley; or, as Ballance suggests may yet be possible, the vestibular nerve, as distinct from the auditory nerve, may be divided before it enters the internal auditory meatus.

ON LEAD POISONING IN CHILDHOOD.*

By A. JEFFERIS TURNER, M.D.LOND., D.P.H.CAMB.,
BRISBANE.

THOUGH lead-poisoning is practically unknown among adults in Queensland, except among those specially exposed to it by occupation, such as painters, yet lead-poisoning among children is not uncommon in every township in Queensland. By not uncommon I mean that every medical man practising among children should probably see several cases every year. The causation of the disease has been ascertained, and that similar cases must occur in all those parts of Australia in which similar conditions may happen to prevail.

The symptoms of lead poisoning in children differ from those found in adults in certain important particulars, which have not yet found their way into the textbooks, and as a consequence the real nature of the affection is very frequently overlooked or misunderstood.

ETIOLOGY.

My experience is confined mostly to Brisbane. I see cases rather commonly in private practice, more commonly since I have come to recognize the milder cases and earlier stages. A few of these cases have come from other towns. The records of the Children's Hospital show that 262 cases have been treated as in-patients since 1891, and at present some 20 cases are being admitted every year.

The cause of lead poisoning among Queensland children has been most convincingly demonstrated by Dr. Lockhart Gibson.¹ Nearly all the dwellings in Queensland are built of wood, and in the towns the wood is covered by paint consisting largely of white lead. Exposed to our hot summer sun this paint rapidly withers and becomes

reduced to a powdery condition. This is particularly noticeable on verandah railings. The verandahs are favourite playgrounds for young children, who clasp the railings with their moist hands, which become covered with poison. Thence it finds its way to the child's mouth, especially in children who suck their fingers or bite their nails. Dr. Gibson's investigations explain:

1. Why the disease is found in children from all towns in Queensland, but appears to be unknown in the country, where the houses are of wood but not painted.
2. Why it is most prevalent in the summer months.
3. Why it frequently picks out one child only in a family, attacking the one who bites his fingers or sucks his thumbs, or who plays habitually on the verandah, etc.

Similar cases must occur in any districts of the other States, if such exist, where the dwelling houses are similar, even though such cases may have never been recognized.

I do not mean to deny that lead poisoning may occasionally but rarely occur among Queensland children from other sources than that here given, but I have no doubt whatever that this is the cause of the endemic prevalence of this form of sickness.

SIGNS AND SYMPTOMS OF LEAD POISONING IN CHILDREN.

There are two signs of lead-poisoning in children that are not, properly speaking, morbid symptoms, but which are of great value as indicating the presence of lead in the tissues.

First, the so-called "blue line" on the gums. A continuous line is rather exceptional in children; what we usually see are small blackish dots at the extreme edge of the gum opposite some of the teeth, more particularly those that are not so clean as the rest. They are frequently minute, and need to be looked for in a good light, and sometimes with the aid of a lens. I repeat, they have to be looked for; on a casual inspection they will certainly be missed. Where there is actual pus exuding from the gum I have seen a dark black line on the edge of the sinus, and even discoloration of the cheek opposite to it, but this is rare. A discoloration of the base of the tooth itself is no sign of plumbism; and doubt as to the site of the blackness may be at once removed by inserting the edge of a piece of stiff notepaper between the gum and the tooth. These dots in the gum are pathognomonic. But they may occur in the absence of symptoms. When a child exhibits symptoms of plumbism an examination of the teeth of its brothers and sisters will sometimes reveal the presence of the dots in them, though they are in apparently good health. This *stigma* of plumbism may, as I have observed, be followed later by the usual symptoms. On the other hand, the complete absence of lead dots is of no importance in diagnosis. The lead dots are particularly likely to be absent if the child has a clean set of teeth.

The second *stigma* of plumbism is the presence of lead in the urine. The detection of traces of lead in this fluid should be the task of a trained analyst. Lead is by no means constantly present in the urine of these children, therefore little weight, if any, should be given to a single or even several negative findings. On the other hand, the presence of lead in the urine is positive proof that the metal has been absorbed

into the system. For clinical purposes an analysis of the urine is, I think, seldom necessary.

1. Gastro-intestinal Symptoms.

These correspond to the lead colic of adults, but are less defined. The child complains of abdominal pain, which is often plainly of a colicky nature. There is no abdominal tenderness, but pressure frequently gives relief. Vomiting, often persistent and lasting for several days, is a usual accompaniment. During this time all food is often rejected, with complete impartiality. The bowels are

* Presidential Address delivered at the Section of Diseases of Children of the Australasian Medical Congress held in Melbourne, October, 1908.

usually constipated, but this is not invariable; sometimes there are rather frequent small stools containing much mucus.

If these symptoms are accompanied by dots on the gums the diagnosis is easy. If the latter are absent it may be difficult, but may often be made with a high degree of probability.

One feature of these attacks is that they are independent of the nature of the food the child has taken, and another is their periodicity. If a child is brought with a history of attacks at intervals of a few weeks or months, during which it is continually vomiting and complaining of abdominal pain, while in the intervals it eats everything without suffering, plumbism should be strongly suspected. If pain in the legs accompanies that in the abdomen, plumbism may be safely diagnosed; and when the child—perhaps after several attacks—begins to drop its toes when walking, there is no longer any room for doubt.

In doubtful cases the fingers should be inspected to see if the nails are bitten, and if the house is visited the condition of the paint on the verandah railings and other parts, together with the habits of the child as to play, etc., should be inquired into.

2. Paralysis of the Muscles of the Limbs.

Lead poisoning and wrist-drop are so closely associated in the mind of the profession that it is necessary to say at once that wrist-drop is *not* the most characteristic paralysis in childhood. It is frequently absent in children under 12 years of age. When present it is never the first paralytic symptom. The feet are invariably affected first, and are invariably the last to recover. This is so in my experience at least.

The earliest muscles to become paretic or paralysed are the tibialis anticus and extensor longus digitorum pedis. The child drops its toes in walking, and the nature of its ailment can be recognized as it walks into the consulting room. There are, of course, other causes of this form of paralysis, such as arsenical and alcoholic poisoning and beri-beri; but I have not so far met with any instance in which these have complicated the diagnosis. The peronei are also frequently attacked and occasionally suffer worse than any other muscles. In the forearm the extensors of the fingers are attacked before those of the wrist, as is the case in adults. Paralysis of the small muscles of the thumb, accompanied by wasting, is often seen in severe cases, and the interossei may be similarly affected. In the muscles of the hand paresis and wasting appear to be simultaneous, and in this respect they differ from the muscles of the forearm and leg.

A very common symptom attending the onset of the paralysis is pain in the muscles of the legs. This comes on especially at night, when the child frets and cries and cannot go to sleep. The pains are usually accompanied by tenderness of the muscles, but may be relieved by warm fomentations. When severe they are accompanied by evident cramp, affecting particularly the calf muscles. I have seen extremely painful cramps of the back muscles, and of other muscles, also, as in a case of which I made the following note during an attack: "The child lies on its face, embracing a pillow with both arms. When the pain comes on the head is thrown back by spasmodic contraction of the back muscles, the muscles of the arm are in tonic spasm, the legs are flexed, and hamstrings forcibly contracted. The legs are tender, and the slightest touch causes the child to cry out. The abdomen is not tender, and stands firm pressure well. The mind is perfectly clear; the child is very intelligent." This was an extreme and very unusual condition.

If the child is removed from the source of the poison, the forearm muscles usually recover in a few weeks, those in the hand more slowly. The leg muscles are much more slow to recover; three months may suffice in recent cases, but some take much longer. Talipes equinus may persist after the anterior muscles have regained contractility, and it is then necessary to divide the tendo Achillis. Complete recovery is usual. In old cases with relapses—in some the history had spread over several years—I have seen apparently incurable paralysis, but in the light of recent advances in the treatment of paralyses I am not sure that any case should now be regarded as hopeless.

3. Diaphragmatic and Cardiac Paralysis.

One of the less frequent symptoms of plumbism is paralysis of the diaphragm, of which I have seen a fair number of cases, but only in patients suffering from the usual paralyses of the legs. In itself it is not a serious symptom, for this paralysis gives rise to no embarrassment of respiration in a child lying in bed, and will, indeed, escape observation unless carefully looked for. Most of my cases were old-standing cases of plumbism, but I have seen diaphragmatic paralysis in a first attack. When it comes on acutely, I regard it with grave anxiety, for two or three times I have seen it accompanied or followed by fatal cardiac weakness. This is characterized by excessive weakness and rapidity of the pulse, intense general depression, and vomiting, without any intellectual disturbance; death occurs usually within twenty-four hours. I am unable to explain these symptoms, but they are very similar to some fatal cases of poisoning by diphtheria toxins, which occur in a late stage of that disease.

4. Remote Effects: Anaemia, Albuminuria, Nephritis.

Old-standing cases of plumbism are frequently distinctly anaemic, with sallow complexions. This is not so in recent cases.

Transitory albuminuria is not uncommon. Chronic interstitial nephritis is, I believe, an occasional but rare complication. A case which ended fatally has been reported by Dr. T. E. Green.²

5. Eclampsia.

Now and again children suffering from chronic plumbism develop eclamptic seizures. These do not differ symptomatically from convulsions due to other causes, but are of a severe type and not infrequently fatal, even when treated with the greatest skill from the onset. I believe that a good many cases of fatal convulsions in Brisbane are the effect of undetected plumbism. A few months ago I was called in consultation to see a boy dying from protracted convulsions. Careful inquiry failed to elicit any exciting cause, but an examination of the gums revealed the typical appearances caused by the deposit of lead sulphide.

6. Acute Optic Neuritis associated with Oculo-motor Paresis.

The far-reaching effects of plumbism in childhood are not yet exhausted. The most insidious and most damaging I have not yet mentioned. There is a totally distinct clinical complex, first recognized by myself long before I had any idea of its causation, and described at the Inter-colonial Medical Congress of 1892 as "a form of cerebral disease characterized by definite symptoms, probably a localized basic meningitis." I mention this purposely, as it is with meningitis and cerebral tumour that this form of lead poisoning is most likely to be confounded. This mistake has been made frequently in the past, and will no doubt be repeated in the future. Nevertheless, the diagnosis of this condition is not as a rule difficult to those familiar with it.

These cases are usually brought to us complaining of headache, which may be severe and persistent, and may be accompanied by vomiting. We observe at a glance that they have an internal squint. Sometimes the squint is the symptom for which they are brought, but on the other hand it may be so slight as to have escaped the mother's observation. On inquiry we learn that the squint is recent, and on examination we find that it is due to paresis of one or both external recti. This ascertained, we proceed to examine the optic discs, and discover optic neuritis, so intense in most cases as to be evident even to the tiro in ophthalmoscopy. This symptom complex is due to lead poisoning. We proceed to verify our diagnosis. In default of any corroborative evidence of lead, we must remember that a cerebral tumour, cerebral tubercle, or cerebral syphilis, might produce exactly these symptoms and no other; but it has happened in all the cases of tumour or cerebral syphilis that I have seen, that other symptoms not characteristic of lead have been present; so that the probability of a case such as I have described, occurring in Brisbane, or any town similarly painted, being due to any other cause than plumbism appears to be very small.

In more severe cases, which are less often seen, the cerebral and ocular symptoms are more pronounced. We

see these children usually in bed. In addition to headache, there may be severe pains in the back of the neck running down into the arms. The head may be retracted. Both external recti are completely paralysed, and some, or all, the muscles supplied by the third nerve (except the levator) may be paralysed also. There may even be immobility of the pupils. These cases are frequently confounded with meningitis. It is a natural, perhaps an inevitable, mistake, but inspection of the gums may save even the inexperienced from error. If the gums are clean the bitten finger-nails may arouse his suspicions. The course of the case is not that of an ordinary meningitis. The child almost always makes a perfect recovery except as to vision. I can remember only one of these cases that proved fatal, unless convulsions supervened, but there is almost always some loss of sight, which may be total.

Blindness due to optic atrophy, and therefore permanent and hopeless, is the unfortunate consequence of a large percentage of these cases of plumbic ocular neuritis. It may occur in the milder cases in which only the optic and sixth nerves are involved; when the third nerve is implicated, escape from at least partial loss of vision is rare. In many cases the blindness is absolute, in some there is only great impairment of vision. The suddenness with which this is lost has struck me forcibly. One day there may be nothing to suggest defective vision, within the next two days the child may be found apparently quite blind. Fortunately the great majority of the milder cases recover perfect vision if they come under treatment early.

It is a remarkable thing that children who suffer from ocular neuritis do not suffer from limb palsy. I have never seen the conditions combined. Dr. Lockhart Gibson has once observed wrist drop in a child suffering from ocular neuritis, and two or three cases in which the limb palsy had preceded or followed ocular neuritis at an interval of many months. Cases of the two forms occurring in the same family are not so rare.

A large proportion of lead poisoning in children take on the form described in this section. Of 89 cases of plumbism admitted during the last four years into the Children's Hospital, Brisbane, 20 were of this variety, that is, 22.5 per cent.

7. Chronic Optic Neuritis and Atrophy without Paresis of Sixth Nerve.

These cases are much less often seen than the preceding. I have no experience of them, and Dr. Lockhart Gibson has only recognized them within the last three years. The symptom complained of is loss of sight, and the ophthalmologist is most likely to be consulted. The course is slow, and they respond well to treatment, if not too advanced. Diagnosis can only be made by finding evidence of lead in the system, or of exposure to the causes of plumbism.

PREVENTIVE AND CURATIVE MEASURES.

There may be, and doubtless are, other conditions attributable to lead than those recognized, but those I have described are sufficient to show that lead poisoning among children is a serious evil. Prevention is easy. Paint containing lead should never be employed on outside surfaces, such as fences, walls, and particularly verandah railings, in places where children, especially young children, are accustomed to play. Zinc-white, or some other paint free from lead, should be substituted. Unfortunately we in Brisbane still from ignorance, no longer excusable, allow our houses to be poisoned traps for children's fingers, and every year furnishes its quota of ill-health and suffering, crippling, hopeless and permanent blindness, and occasionally death as the consequence. This is certainly a matter which calls for legislative interference.

The curative treatment consists essentially in removing the child from the source of the poison. We adopt also other measures calculated to encourage the elimination of lead from the system, but to what extent these are efficacious must be a matter of doubt. By themselves they are useless. Removal of the child into a hospital is a short way of taking it out of danger. But after its discharge it will surely relapse if the home conditions remain the same. We must find out exactly where the child got the poison, and warn the parents to keep him away from

it, remembering that lead paint is only dangerous (1) when it is fresh and sticky, or (2) and more especially when it is dry and powdery. It is also well to break the child of the habit of nail-biting or thumb-sucking, which by the way is no easy task. The most effectual method is to put straight splints over its elbows. This may seem harsh treatment, but milder methods usually fail.

A CASE OF CROSSED PARALYSIS.

By GORDON LAMBERT, M.D. CANTAB.,
SELSEY, SUSSEX.

The following case, though not very unusual, presents, I think, certain features of interest:

W. J., aged 59 years, farmer and dairyman, had been very "irritable" for some days before February 7th. On that day he got out of bed at 4 a.m. to pass urine. Immediately after doing so, he became very giddy and fell down; but he did not lose consciousness. He returned to bed, with assistance, and afterwards insisted on making several attempts to walk. I was summoned to him at 8 a.m., and I found the following physical signs:

Nervous System.—Upper segment paralysis of the face on the left side, partial paralysis of the right motor oculi nerve, ptosis, slight divergent strabismus, limitation of movements of the eye (chiefly upwards), diplopia. On my arrival the right eye was completely closed; but the patient persisted in making voluntary efforts, until he completely raised the upper eyelid. The pupils were equal and reacted to light and accommodation. The left arm and leg did not show any loss of motor power; but the knee-jerk was distinctly brisker on the left side.

Heart.—Apex beat not palpable. Apex localized by percussion and auscultation in fifth left interspace, nipple line. Heart sounds faint and distant; aortic second sound not accentuated. No bruit.

Pulse.—Regular, 90 odd, of small volume, moderate tension. Radial arteries tortuous and uniformly thickened; no discrete, nodular thickenings.

Urine.—Specific gravity, 1018. No albumen. (Urea not estimated.) Patient has passed urine during the night for several years, nearly every night. He estimates that he passes from three to four pints per diem.

Previous History.—The patient had been a temperate man, and had done a great deal of heavy manual work. He had had one severe illness only, an attack of influenza 16 years ago, during a severe epidemic.

Progress and Result.—Motor power was rapidly regained during the first week, and on February 22nd the facial paralysis was no longer evident. Diplopia persisted; but the limitation of movements of the right eye was distinctly less. The ptosis had quite disappeared. The pulse was regular, 82, of moderate volume and tension. The physical signs in the heart were as before. The urine-specific gravity 1018—contained no albumen.

The case is clearly one of crossed paralysis due to a lesion in the right crus cerebri, involving the fibres of the motor oculi nerve and the facial fibres of the pyramidal tract. It is justifiable to assume that the nucleus of the motor oculi is not involved.

The chief interest centres on the nature of the lesion. Is it a very limited hæmorrhage, presumably from one of the deeper small arteries (of the "ganglionic system") or thrombosis of such a vessel? Arterio-sclerosis is certainly present; but the condition of the heart and pulse, taken in conjunction with the history of severe influenza, seems to make the probability of hæmorrhage doubtful. The onset is interesting. The giddiness and falling are, of course, not unusual after evacuation of the bladder—the splanchnic vessels being rapidly filled with blood and transient ischaemia of the brain established. There is no evidence that the act of micturition is accompanied in this patient by any special effort of straining, which might produce a hæmorrhage, that is, by raising tension, in spite of the upright position and the evacuation of the bladder. The involvement of the facial fibres and the escape of the arm and leg in a lesion of the crus cerebri is also interesting, as indicating very limited damage.

The Committee on Legal Affairs of the Massachusetts Legislature, to which the Antivivisection Bill was referred this year, has reported leave to withdraw. This, it is said, is the eleventh or twelfth time that such a bill has been presented to the legislature and has met with the same fate in committee.

MEDICAL, SURGICAL, OBSTETRICAL.

ACUTE ASCENDING PARALYSIS.

THE case of acute ascending paralysis reported by Dr. Dean in the BRITISH MEDICAL JOURNAL of February 27th, p. 529, reminds me of a case which occurred very early in my professional career, fifty-three years ago. I had joined the Indian Medical Service the previous year, and had proceeded to Kurrachi, in Scinde from Bombay, on general duty, as it was termed, before being definitely attached to a regiment as medical officer. In 1856 I was temporarily placed in charge of the civil medical duties of the station, which included the members of the staff of Government House, and whilst so serving General John Jacob, Commandant and Political Officer of the Frontier, came down to act as Commissioner in Scinde during the absence of Sir Bartle Frere in England. I was called to see a native officer on his establishment who had been seized with paralysis. I found that he had but recently recovered from an attack of choleraic diarrhoea, when symptoms of loss of power over the lower extremities had set in, commencing with the feet, and rapidly—that is, within a day or two—had extended upwards.

When I saw him the paralysis of motion was complete as high up as the diaphragm, and respiration was becoming difficult, but the arms were only slightly affected. I learned that the symptoms had very rapidly extended during the past few hours. It occurred to me that this was a case in which strychnine might be of signal service, and I proceeded at once to administer it in full doses, and pushed it in my youthful zeal to an extent which in later years I might have hesitated to adopt. The treatment was entirely successful; within a few hours the upward ascent of the paralysis was stayed and improvement began and progressed downward as steadily as the attacking symptoms had done in the opposite direction, until he was, in the next twenty-four hours, able to sit up in bed, then regained the use of his legs, and within a few days had recovered from any symptom of paralysis.

This was ten or twelve years before Landry published his notable paper on this disease, and although I have since had great opportunities of watching disorders of the nervous system I have never personally met with another case. It may possibly have been a case of spontaneous recovery, but the sequence of events did not suggest this to my mind at the time. I may, perhaps, be allowed to add that the case proved a stepping-stone in my career, which led to a series of kindly acts of good fortune whose influence I can trace through a long period of service.

HENRY COOK, M.D., F.R.C.P.,
Surgeon-General (retired).

Lee-on-the-Solent.

ETIOLOGY OF OXALURIA.

IN this part of the Sylhet district of Eastern Bengal there are several races—Bengalis, Manipuris, Tipperas, Kookies, and Coolies, the last imported natives of the Central Provinces.

None of these races suffer from renal gravel in any form except the Manipuris, among whom it is very common. The Manipuris, the Tipperas, and the Kookies are all tribes of Mongolian origin, closely related in manners, customs, and language, and in appearance are the same people.

All the afore-mentioned races live under more or less the same circumstances, being agriculturalists. They have all more or less the same habits, with one great difference—namely, the Manipuris live on nothing but vegetables and fruit; they eat nothing in the nature of flesh, not even eggs, except one caste amongst them, which eat sometimes putrid fish. The gravel they suffer from is calcium oxalate. The urine is always very acid, contains blood and enormous quantities of oxalate of lime crystals, ranging in size from those requiring a one-sixth objective to a stone large enough to temporarily stop a normal urethra.

These urines when looked at fresh contain no other crystals. They complain of the ordinary symptoms of renal gravel. The symptoms and the pathological condition of the urine entirely disappear on the administration of arotropine and potassium citrate.

All the water in this part is prominently deficient in calcium salts when examined chemically. The soil is peat for about 20 ft. deep, and underneath that is yellow clay for huge depths. Man, clinically speaking, suffers greatly from the want of lime. He gets covered with boils, carbuncles, etc.; he suffers from conditions clinically allied to scurvy. Imported Australian horses suffer from similar diseases. All these ills in man and horse are quickly cured by liberal doses of calcium chloride, and are also prevented by regular doses of this salt. If imported horses are given slaked lime in their water they remain healthy. This clearly shows that for the animal economy there is a great deficiency of calcium in both the water and vegetation of this neighbourhood. Therefore, for the formation of calcium oxalate crystals excess of calcium is not required; some other factor or factors must be the cause.

Considering the above remarks on the similar habits and surroundings of these different races, and of three which are of the same blood, and that only the purely vegetable-eaters suffer, and that those who eat along with their vegetables a certain amount of animal food do not suffer, and also considering the great deficiency of lime here, one is driven to the conclusion that a purely vegetable diet is here, at all events, the cause of oxaluria.

Chandkila P.O. R. W. BURRITT, F.R.C.S.I.

ERYTHEMATOUS ERUPTION FOLLOWING NITROUS OXIDE ANAESTHESIA.

NITROUS oxide gas was administered in the usual manner (valves) to a young man aged 21, perfectly healthy and free from organic disease, but of neurotic temperament. At 10.45 a.m. six teeth were extracted, and the operation calls for no comment; the patient was perfectly quiet throughout it. Recovery was normal without excitement, and haemorrhage soon ceased. The patient rested for an hour and a half, and then went home some few miles by tram.

On arrival at his destination, he felt some slight pain in the jaw with some vertigo, and in consequence lay down again. About 3 p.m. a dusky red patch appeared on the right cheek, in colour resembling a birth mark; the margin was sharp but irregular, not raised, and unattended by any sense of heat or itching. This faded in about one hour, and the patient partook of a little bread and milk. At 6 p.m. there was a feeling of slight nausea, and he vomited once. Almost concurrent with this a rash appeared all over the face. It had the same deep-red appearance as the former; at first mottled, it slowly became uniform. Circumoral and nasal pallor, with a well-defined irregular margin all round, was marked. The discoloration involved the ears and forehead, but did not extend on to the neck or scalp. There was no rash else where. It faded completely in two hours, and has not recurred.

I have been unable to find any other factor to account for this, and there had been no previous attack. The patient was in my company from 6 p.m. the preceding evening, till the final fading of the rash, so I can vouch personally for all the circumstances. I am unaware of any similar instance of an eruption following nitrous oxide.

London, W.

ACUTE RHEUMATISM WITH UNUSUAL SEQUENCE OF COMPLICATIONS.

THE following case is remarkable, owing to the occurrence of so many separate complications in one patient at one time, and yet all appearing at short though well-marked intervals.

On December 8th I was called to see E. W., aged 18; he had rheumatism in both wrists and knees and at times in the ankles; the tonsils had been "sore" for a day or two. The temperature was 100°. These symptoms yielded in the course of a few days to the ordinary treatment by milk diet and sodium salicylate. The temperature was down to normal in three days, and on December 21st the patient got up without leave.

On the evening of December 23rd I was sent for and found him out of bed, with a very flushed face, dry skin, and rapid and painful respirations. The temperature was 102.6°. There was tenderness over the outer half of the left thorax, which was dull on percussion; on auscultation,

a slight pleuritic rub was heard, but no riles or rhonchi anywhere; the heart sounds were perfectly normal. Next day the pleurisy had extended slightly, and there was now a well-marked triangular dullness over the cardiac region and a distinct pericardial rub. The temperature was 102°. The same evening slight crepitations were to be heard over the right base behind.

On December 25th the pleuritic pains were less, but there was pain over the heart area and riles, loss of tactile vocal fremitus, and dullness over the entire lower lobe on the right side behind.

On December 29th pleurisy had nearly cleared up, but riles and dullness appeared over a small patch of the left lower lobe behind. The temperature remained very steady at 102°. The patient was now taking *sod. salicylate* gr. x every four hours, and from this day started brandy $\frac{5}{8}$ every four hours; the precordial area was painted with *linimentum iodi* fort.

On December 31st the pericardial rub had almost gone, but in its place appeared loud presystolic and systolic mitral bruits.

On January 1st, 1909, the patient was put on *tinct. digit.* and *tinct. nuc. vom.* with *sp. aeth. nit.* There was pain over the heart, and the impulse was now outside the nipple line.

On January 7th the temperature came down to 101°. The ears were very blue, but breathing was not very difficult.

On January 9th the temperature was 99° and the pain had nearly gone. From this date the patient made an uninterrupted recovery, except that after his first walk outdoors on January 25th he had a slight return of rheumatic pains in the knees which quickly yielded to *sodium salicylate*. On January 22nd the heart's impulse was in the nipple line, and by February 2nd the impulse was normal and all bruits had entirely disappeared.

The point chiefly noticeable in this case is the well-marked sequence of rheumatism, pleurisy, pericarditis, and pneumonia of first one and then both sides, and finally rheumatism again. The delayed crisis was due to the onset of pneumonia in the left lung five days after its appearance in the right lung. The excellent effect of brandy was very apparent.

Lowestoft. C. M. L. COWPER, M.R.C.S., L.R.C.P.

UNNA'S METHOD OF TREATING ULCERS OF THE LEG.

I was very interested in Dr. Pernet's paper (p. 463), as I have for some time past been carrying out a modified form of Unna's treatment.

When I was in South Shields Hospital we added, at Dr. Hunter's suggestion, some charcoal to the paste we were then using. This addition causes the paste, or "splosh," to be of a porous nature, and the occluded oxygen helps to keep the ulcer sweet.

Formula.

Charcoal	18 parts
Zinc oxide	6 "
Boric acid	6 "
Gelatine	16 "
Glycerine	20 "
Water	50 "

Soak gelatine and portion of glycerine and water for twelve hours. Make paste with all remainder. Mix together and heat on water-bath, stirring. Pour into shallow vessel.

The method of using also varies. A carbolie (resin) bandage is wound tightly round the leg covering the ulcer, and going a handbreadth above and below it. The "splosh" is painted well over the site of the ulcer. If much discharge is feared, it may be dabbed with cotton-wool.

An ordinary bandage is wound round all. If the ulcer is much punched out, I have been in the habit of putting a small piece of the carbolie bandage, cut to size, on its bed. This avoids leaving a space in which pus might gather, which I take it is the object of the flattening of the edge Dr. Pernet describes.

To begin with, I generally order boric fomentation for a week or so to clean the ulcer, or if it tends to be sluggish I find red lotion helps. At first the paste is left on for a week; later, when healing well, it can be left a fortnight.

The waxy nature of the bandage prevents it adhering and tearing off the epithelium. The method has not only

been the means of much saving of time and labour, but many ulcers of years' duration have quite healed up, and that usually while the patients were on their feet.

It is advisable in chronic cases which have healed to bandage the leg firmly for a considerable period to prevent recurrence. If ulcers are recent (and not haemorrhagic) simple dressing, venous congestion combined with rest in bed, appears to me to be the quickest method of obtaining healing.

Reports

ON

MEDICAL AND SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF THE BRITISH EMPIRE.

CHRISTCHURCH HOSPITAL, NEW ZEALAND.

PERFORATION OF INTESTINE BY PLUM STONE.

(By P. CLENNELL FENWICK, M.D.(N.Z.), F.R.C.S. Ed.,
Honorary Surgeon to the Hospital.)

H., a very fat woman, aged 38, was admitted under my care on February 8th.

On admission she was in a state of semi-collapse, cyanosed, with feeble pulse (144), subnormal temperature, and cold, clammy skin. She was quite conscious, and gave her history clearly.

History of Illness.

She had been in good health until February 5th, when she had severe pain in the lower part of the abdomen, and vomited. The bowels were not opened on this day, and remained unopened till admission. The vomiting returned on February 6th and continued till the day of admission. The vomit was foul-smelling, yellow, but not distinctly faecal in character.

Condition on Admission.

The abdomen was not markedly distended; it was soft, and palpation was painful. A large area of hardness was felt, chiefly on the right side. There was no sign of fluid in the abdomen. The patient was so fat (weight 15 st.) that examination was difficult. The rectum was empty. Vaginal examination, which was painful, was negative.

Operation.

As the patient was not then in a condition to undergo operation, I decided after consultation to wait for a few hours to see if she would rally. At 9 p.m. she had rallied enough to bear an anaesthetic, and I opened the abdomen. A great quantity of most foul-smelling pus escaped, and I found intense peritonitis of all the small intestine. The coils were matted together, and in some parts were black and lustreless. I could not find the appendix, and, not wishing to delay, I put a Paul's tube into one coil of the intestine, which seemed less inflamed than most of the rest, and drained by a tube pushed down into the pouch of Douglas. The patient died some hours later.

Necropsy.

On *post-mortem* examination by Dr. Crooke, R.M.O., a condition of extremely severe peritonitis was revealed. The entire small intestine shared in the inflammation. In parts the gut was almost gangrenous. The large intestine was normal but very distended; the appendix was normal. Twelve inches above the anus a gangrenous patch was found measuring about 2 in. by 4 in. In the centre of this area was a perforation which admitted the tip of the finger, and lying in the gut just underneath the perforation was a large plum stone.

REMARKS.

Neither my colleague, Dr. Nedwill, jun., nor I had met with a similar case, the perforation being so near the anus that it seemed curious that the stone had not been passed in the ordinary way after having travelled so far.

Reports of Societies.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

(Continued from Section of Surgery.)

Friday, March 19th, 1909.

Mr. E. H. TAYLOR in the Chair.

A New Voice Machine.

Mr. R. H. Woods exhibited a patient fitted with a new apparatus for voice production. Owing to the discovery of an extensive squamous carcinoma, the whole larynx had been extirpated. The trachea was sutured to the skin, and the sac of the pharynx completely cut off from communication with the respiratory tract. Thinking how to enable the patient to speak, it occurred to the speaker to try to convert the sound made by a reed into speech. Accordingly, he fixed a reed in a tube. By putting it into the nose and dropping it over the soft palate, and by putting the other end into the trachea the patient was able to blow and make the reed vibrate. A valve was used to take in the air, and when he had his chest full he put his finger to the end, and the air was pressed into the tube. The method of inserting the appliance was then shown, and the patient after a salutation to the section, counted from one to ten.

Mr. DEMERSY said the case showed the results that could be obtained in laryngectomies when the pharynx was cut off from the respiratory tract. The real success of such a case was due to the avoidance of the danger of pneumonia, which killed 9 out of 10 patients formerly. Professor Gluck had performed 21 complete laryngectomies in the past year or two, and had not had a single death. It was too soon, however, to judge of the question of recurrence.

Mr. W. L. MURPHY suggested the trying of a smaller tube.

The CHAIRMAN said he was much struck by the comparative ease with which Mr. Woods was able to close the pharyngeal tube.

The SECRETARY inquired as to the effect of the operation on the man's hope of life. Horses which were tracheotomized improved for a time, but after a while went rapidly to the bad.

Mr. STOKES asked if the patient could cough.

Mr. Woods, in reply, said there was no trouble in getting a pharyngeal wall; even after the larynx was taken away there was plenty of wall to complete a very good tube. Before doing the extirpation he thought it wise to give the patient an antistreptococcus vaccine so as to raise his opsonic index, and his temperature only rose to 100° for two days and then fell to normal. This was, under the circumstances, remarkable, and he thought some of the credit was due to the preliminary vaccination. The tube was sufficiently small to pass through the nose, and a smaller one would require a smaller reed, which would give less power to the voice. He had had a case of tracheotomy about fifteen years ago, and the man was in the best of health though still wearing a tube. The man before them could make a respiratory effort capable of clearing off any secretion in his windpipe. He was fed after the operation by a tube through his nose. This was kept up until he was able to swallow, about ten days afterwards.

Hydronephrosis and Appendicitis.

Mr. E. H. TAYLOR exhibited an ectopic hydronephrotic kidney removed from a young woman about a fortnight before. The clinical symptoms were strongly indicative of appendicitis. On palpation over her right iliac fossa he was able to determine deep fluctuation, and as she appeared to be very ill he decided to operate that evening, and to cut down over the fluctuating area with local anaesthesia. He was surprised to reach the parietal peritoneum without any evidence of pus. When he opened it his finger passed over a surface that was bigger than a normal caecum, and he thought it might be an ovarian cyst with a twisted pedicle. He extended the incision under chloroform, but found no pedicle. He punctured a large swelling which was fluctuating and tense, and a quantity of fluid escaped. The tissue at the edge of the opening was evidently renal. He put a tube into the

kidney and drained the hydronephrosis, and after ten days removed the kidney, having previously satisfied himself that the left kidney was healthy. The case showed that even where all typical features of appendicitis were present, they might be dealing with a case that had nothing whatever to say to either the caecum or appendix.

Dr. PEACOCK said he saw the girl only three days before he sent her into hospital, and he never was more positive in his life that he was dealing with appendicitis. He had great hopes, from past experience, that the girl would live a long life with only one kidney.

The SECRETARY said the frequency with which appendicitis was met with made them tend to come to the conclusion that most right-side pains were due to it; but he had seen a fair number of cases which proved to be otherwise. He had operated on somewhat similar cases as regards the pathological findings, though the symptoms were not the same. In one case there were oxalate of lime stones, which had probably excited a considerable amount of inflammatory reaction, and led to narrowing of the ureter.

Mr. TAYLOR, in reply, said the strength of novocain used in Berné was 1 tabloid dissolved in 10 c.cm. of sterile water. He had used it approximately at that strength, but often weaker. When getting down through the muscles towards the parietal peritoneum he always injected freely, and tried to produce oedema of the extra-peritoneal tissue. There was some pus mixed with the urine in the distended pelvis. After the operation the temperature rose to 100°, but the morning after the pain had gone, and the temperature fell to normal and remained so. The wound had practically healed, and the patient was perfectly well.

GLASGOW MEDICO-CHIRURGICAL SOCIETY.—At a meeting on March 19th, Dr. T. K. MONRO, Vice-President, in the chair, Mr. FREELAND FERGES showed a number of photographs of cases and a patient on whom he had performed his operation for *Ptoxis*. The operation consisted in the resection of the tarsus and of excision of a large part of it, with the suturing of the remaining portion to the occipitofrontalis muscle. With this operation the patient had considerable power both of shutting and of opening the eyelid. He pointed out that the operations of Worth and Harman were essentially good, but that they ligatured the lid permanently open. The operation of Hess, although differing in principle from these operations, also permanently fixed the eyelid in an open position. Pagenstecher's operation was one which he considered should never be performed. Cicatricial contraction by the introduction of thread sutures could, in his opinion, only take place when the sutures were not perfectly sterile. Dr. W. S. SYME made a communication on some points in the surgery of the sphenoidal sinus, based on an examination of 155 adult skulls. The average distance from the anterior nasal spine of the maxilla to the opening of either sinus was 2½ in., the extremes being 2½ to 2½ in. To the posterior wall the average on the right side was 3½ in., and on the left 3½ in., the extremes 2½ to 3½ in. In only one-sixth of the skulls was the posterior wall distant less than 3 in., and in none was the opening distant as much as 3 in. As a rule, the posterior ethmoidal cell did not extend beyond the anterior wall of the sphenoidal sinus. Well-marked osseous septa within the sinus were found in 13 cases. Suppuration in these cavities he considered was much more common than was generally supposed. Mr. J. HOGARTH PRINGLE, in a paper on the treatment of *Fractures of the long bones*, advocated Bardenheuer's method of extension by very heavy weights, sometimes as much as 35 lb., applied so as to correct lateral displacement and rotation as well as shortening.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.—At a meeting on March 4th, Dr. DAVID RENNET, President, in the chair, the following were among the exhibits:—Mr. H. M. W. GRAY: A case of chronic obliterative *Lymphangitis* of right leg, which had come into hospital for amputation owing to the pain and distress caused by the swelling of the leg. Sampson Handley's operation was done, the strands of silk being passed subcutaneously from the ankle to above the knee by means of a Babcock's vein extractor. Great relief had followed and almost entire disappearance

of the swelling, though the patient had not so far used the leg very much. As organisms are frequently found in the fluid in these cases, and as the operation is liable to be followed by inflammation, injections of streptococci and staphylococci was done before operation, and no inflammation had followed. Mr. Gray also showed a case after operation for traumatic deformity of foot, and a case of tumour of lower jaw, probably gumma. Dr. GEORGE ROSE: A number of cases of *Congenital dislocation of the hip* in patients of various ages treated by Lorenz's method, where very good results had been obtained. Dr. ASHLEY MACKINTOSH: A case of *Ulnar paralysis*, purely motor and probably traumatic; also a case in which the probable diagnosis was early stage of *myasthenia gravis*. Dr. HENRY PETERKIN: A case of *Rodent ulcer* inside the external auditory canal; he could find no record of a tumour of this nature in this region. Mr. J. SCOTT RIDDELL: (1) A case of *Double talipes equino varus*, apparently congenital. The left foot had been operated on with excellent result. Patient had now returned to have the other foot done. (2) A case of extensive *Necrosis of lower jaw*, with the sequestra which had been removed. (3) A case of *Caries of cervical vertebrae*, with a peculiar dislocation forwards of the atlas on the axis; there were no pressure symptoms then, and, after being in hospital for treatment from March, 1908, till June, he resumed his occupation as a clerk. In November he had a fall in the street and had to be carried home, and was admitted to hospital three weeks later with almost complete loss of power in his limbs; cranial nerves and sensation unaffected. He could with difficulty lift his arm as high as the shoulder, and his grip was very feeble. He could move his legs about when in bed, but could not stand or walk. Knee-jerks plus ankle-clonus present, and slight sluggish Babinski. There were marked arm-jerks and wrist-jerks; sphincter control unaffected. No reaction of degeneration was found, but responses of right arm were feebler than those of left. The patient slowly recovered, and had now almost full control of limbs. (4) A patient who, after a difficult labour in November, developed *Pneumonia*, and later a tumour was discovered in the right flank apparently connected with the uterus, though exactly how could not be determined. She had considerable pain and tenderness in the region of the tumour, which was about the size of a large cocoa-nut and of indefinite outline. Percussion over it was dull, and liver dullness was continuous with it, but the note between the tumour and the pelvis was distinctly tympanitic. A sort of pedicle could be felt running down from the tumour into the pelvis. Temperature and pulse were high at first, but came down as the chest condition improved. Blood count after pneumonia had cleared up was: white cells 12,000, with 79 per cent. polymorphs. Urine normal in quantity, acid, trace of pus; no vomiting, slight constipation, no vaginal discharge. On January 16th abdominal section was done, and it was found that the uterus, along with right ovary and tube and appendix, were fixed in one mass to the under surface of the liver and the abdominal wall, and all were in a state of suppuration. Hysterectomy, salpingo-oophorectomy, and appendectomy were performed; the wound was drained, and the patient was shown with the wound practically healed and in good condition.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—At a meeting on March 17th, Dr. P. BOOBYER, President, in the chair, Dr. A. STANLEY GREEN (Lincoln) showed a series of lantern slides and photographic prints illustrating the value of *Röntgen examination* in some conditions of diseased bone. Amongst the examples shown were instances of osteitis due to injury, tubercle, syphilis, etc., besides Charcot's disease of the joints, rachitic changes, and several cases of sarcoma in close relation to bones. A most instructive case was related and illustrated, in which an examination of the foot by Röntgen rays showed the scaphoid bone to be the seat of two abscesses. Guided by this, the surgeon was able to reach both abscesses through a single opening drilled in the bone without implicating in any way the neighbouring joints. Dr. R. P. PURVES (Lincoln), in a paper on cases of *Gall stones*, described one in which 273 stones were removed by him at an operation; the gall bladder was of an hour-glass shape as the result of omental adhesions. This patient

always seemed better when following Dr. Haig's diet, and relapsed if it was not adhered to. In a second case four large stones were found in the common duct, but jaundice only appeared at quite a late stage, three weeks before operation. A third case illustrated the fact that gall stones gave rise to indigestion and vague pains after meals. Besides jaundice and tenderness, there were referred pains and marked wasting in this case. At the operation, the hepatic, cystic, and common ducts were all full of stones. A fourth case, in a man of 50, with a history extending over several years, was specially interesting as haematemesis occurred after the operation and retinal haemorrhages. Despite these complications he recovered. In discussing this haematemesis the author argued that its real cause was almost certainly of an infective, septic nature. In reply to the discussion, Dr. PURVES laid stress on pain referred to the post-hepatic region in gall-stone cases. It was distinguished from that of lumbago by being confined to this level on the right side.

CLINICAL SOCIETY OF MANCHESTER.—At a meeting on March 16th, Dr. J. J. COX, President, in the Chair, Dr. P. R. COOPER reported a case of *Eclampsic coma* occurring three weeks after delivery, and cured by lumbar puncture. The patient was seen in her first pregnancy. Albumen was found in the urine at the sixth month; she had eclampsic seizures at full term, and was delivered of a living male child, after which the fits ceased, and the albuminuria disappeared. The second pregnancy terminated at seven months, and she was delivered of a stillborn child. No albuminuria and no fits. Nine days after the patient had some paresis, and her mental condition was not quite clear. Three weeks after confinement she came downstairs, when she vomited and became drowsy. Later albuminuria set in, and she became comatose. There was no improvement in spite of the usual treatment. Lumbar puncture was performed, 2 to 3 drachms of cerebro-spinal fluid being drawn off, and saline injected under the breasts. Two days later lumbar puncture was repeated, and further 2 to 3 drachms of cerebro-spinal fluid withdrawn. After this the fits ceased, and the patient made a gradual recovery. Dr. REYNOLDS, in some observations on the diagnosis and treatment of *Migraine*, drew particular attention to the less common varieties of auræ that might precede the typical headaches. Numbness and tingling in the fingers occurred not infrequently. Transient paralysis of the muscles supplied by the third nerve was a rare form described by Charcot, and a case was cited illustrating this variety. As regards treatment, the synthetic drugs were of paramount importance, antipyrin was usually the most valuable, but some patients responded better to phenacetin, aspirin, or pyramidin. The drugs must be exhibited early in the attack to be efficacious.

MANCHESTER PATHOLOGICAL SOCIETY.—At a meeting on March 16th, Dr. MILLIGAN, President, in the chair, Dr. WILKINSON described a case of *Acute Hodgkin's disease*. The patient was a man, aged 28. The illness began early in September with fever, some vomiting and diarrhoea, and slight delirium. After four weeks he had recovered sufficiently to go away for a holiday, but a week later the illness recurred with more severe symptoms and enlargement of the glands of the neck. There was marked anaemia. He spent the last week of his life in the Manchester Royal Infirmary—December 15th to 22nd—in a typhoid state; continuous temperature, 101° to 103.4°; pulse, 120 to 150; respirations, 40 to 50; chain of glands behind sterno-mastoid and glands under lower jaw enlarged on both sides, spleen and liver palpable, some abdominal discomfort and diarrhoea. Widal reaction negative. Blood-count: reds, 4,432,000; whites, 8,000; haemoglobin, 58 per cent.; marked polychromatophilia. The *post-mortem* appearances were described by Professor Lorrain Smith. The case showed a moderately soft and partly necrotic tissue replacing the lymph glands, affecting (a) the coeliac group, and forming a large tumour-like mass in and behind the smaller curvature of the stomach; (b) the glands along the aorta throughout its entire length; (c) the glands of the neck; and (d) the glands of the groin. The enlargement of the coeliac glands was the most conspicuous change. There

was very slight enlargement of the mesenteric glands. The liver was studded with minute white rounded masses of tissue of the diameter of a small pea. Amongst these were a number of larger masses up to the size of a walnut, and one or two of them showed umbilication. The white tissue formed in definite masses closely simulating deposits of malignant new growth. The spleen was moderately enlarged, and studded with large nodules closely resembling tumours of secondary origin. The lungs, heart, kidneys, stomach, and intestine were not affected. The microscopical examination of the new tissue showed the characteristic proliferation of large endothelial cells, but there were very few giant cells and eosinophile cells. Dr. EUGENE YONGE, in a paper on the association of *Deformities of the jaws* with nasal obstruction in children, referred to some of the difficulties in connexion with the usual theory that mouth-breathing, due generally to the presence of adenoids, was the cause of the deformities. Dr. R. W. MARSDEN mentioned 2 cases of *Calcareous degeneration* of the middle coats of the medium-sized arteries. In both instances the degeneration had reached a high degree, the men being of the poorer class, aged 49 and 67 years, and suffering from pulmonary tuberculosis. Attention was drawn to the distribution of the disease, the arteries of the limbs being chiefly affected. In one case the small vessels of the hands and feet were healthy, but in the other both palmar and plantar arches were affected. In both cases the cerebral vessels were practically free from degeneration. The author suggested that the particular form of the toxin producing the affection might play an important part in the peculiarity of distribution.

LIVERPOOL MEDICAL INSTITUTION.—At a clinical meeting on March 25th, Mr. BICKERTON, President, in the chair, the following were among the exhibits: Dr. STOFFORD TAYLOR and Dr. R. W. MACKENNA: (1) *Farus* affecting the thighs and legs of a steward from an emigrant ship—the scalp and other parts of the body were free; (2) rodent ulcer treated successfully with zinc ions; (3) psoriasis of the face occurring in women; (4) psoriasis in a man accompanied by syphilis; (5) dermatitis following the use of a proprietary ointment; (6) wax casts modelled from their own cases, illustrating the cutaneous lesions of syphilis. Dr. LOGAN: A case of *Bilateral asymmetry*, which he regarded as hypertrophy of the whole of the right side. The child was 15 months old, and the difference had been noticed since birth. During the last five months the right limbs had grown more than the left, but the head had become more symmetrical. Dr. C. E. P. FORSTH read a note on the presence of *Tubercle bacilli in the blood* in tuberculosis. The blood of twelve patients was examined. Ten of these were undoubted cases of pulmonary tuberculosis, and in all the organism was found in the blood. The blood was drawn from a vein in the arm. In one case phagocytosis was noticed, and only in one was there any evidence of mixed infection. None of the cases were rapidly progressing cases, or cases of general tuberculosis. Of the two cases in which no bacilli were found, one was probably not tuberculous, and the other had physical signs of phthisis, but no bacilli in the sputum. These cases went far to confirm Rosenberger's observations—for example, as to the use of vaccine therapy in this disease. Dr. HENRY CLARKE read a note on three years' experience in *The use of tuberculin*. His conclusions were: (1) That tuberculin was best administered by the German intensive method, the dose being given at short intervals of one to two days, and rapidly increasing up to 1 to 2 c.c. of the original solution; (2) that doses given by the mouth had the same effect as when given subcutaneously; (3) that the temperature and clinical conditions were as delicate a guide to treatment as the opsonic index; (4) that new tuberculin (bacillus emulsion) was the most effective preparation; (5) that it should be prepared from human bacilli in dealing with disease produced by these bacilli; (6) to determine the variety of bacillus he recommended von Pirquet's cutaneous reaction; (7) he considered tuberculin a useful drug but not a substitute for good food and fresh air. Dr. HILL ARNAB referred to a case which he reported ten years ago which completely recovered under treatment with tuberculin TR; subsequent experience,

however, had not confirmed him in its use. He did not consider that inoculation experiments had established a vital distinction between the bovine and human varieties of tubercle bacilli. He advocated a further trial of tuberculin treatment on the German intensive lines.

NORTHUMBERLAND AND DURHAM MEDICAL SOCIETY.—At a meeting in Newcastle, on March 11th, the following were among the exhibits:—Dr. DAVID DRUMMOND: (1) A typical case of *Acromegaly* in a coalminer aged 40. Up to 19 years of age he was quite normal, and since the age of 21 he has observed comparatively little change. He suffered from headache, but was without vomiting or visual defect. There was no sugar in the urine. (2) A male child, aged 7, who had a *Chronically-distended bladder*, which occupied the greater part of his abdomen. Dr. R. A. BOLAM: A case of *Lupus erythematosus* of face and hands complicated by psoriasis. Dr. BEATTIE: A case of *Osteo-arthritis* due to the gonococcus, the infection dating back nine years. There was a typical osteo-arthritis of the knee-joint. Mr. H. B. ANGUS: (1) A man after recent removal of the scapula for sarcoma. The operation left the acromion and coracoid processes, which he thought was an improvement. (2) A patient with an old fracture of the femur with an unreduced sciatic *Dislocation of the hip-joint*. An attempt was made to reduce it three months later, but the bone was again broken. An open operation was carried out, but it was found to be impossible to reduce the dislocation so that the head of the femur was removed. Mr. W. E. HOME: (1) A *Cretin*, aged 16, who presented the appearance of an infant of 2 years. The administration of thyroid extract improved it as regards its limited intelligence and the condition of the skin. Mr. JOHN CLAY: Specimens of excised gall bladders. He took a very moderate view of the operation of *Cholecystectomy* and thought the main indication was a gall bladder which had a stone impacted in the duct with the presence of clear mucus. He also urged the importance of not removing the gall bladder if there was any chance of a permanent obstruction of the common bile duct. Mr. A. M. MARTIN: A case in which a *Splenectomy* had been performed for wandering spleen. Mr. N. G. RICHARDSON read a paper on post-operative tetanus.

NORTH OF ENGLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.—At a meeting held at Sheffield on March 19th, Dr. J. W. MARTIN (Sheffield), President, in the chair, the following were among the exhibits and communications: Dr. A. J. WALLACE (Liverpool) showed a glass *Vaginal nozzle* which he had removed from the bladder by the vaginal route. The nozzle was 5½ in. in length and ¾ in. in diameter. It had slipped into the bladder, seven weeks previously, during the process of vulval douching, by a nurse, of a recently confined woman. Mr. ARTHUR CONNELL (Sheffield): A case of complete *Torsion of the internal genitalia* with a large interstitial fibroid. The patient, a spinster of 50, had suffered, on several occasions during the previous five weeks, from subacute attacks of abdominal pain and vomiting, which had always commenced during defaecation. Her medical attendant had found an abdominal tumour of about the size of a six months pregnant uterus. The last attack was the most severe, and had lasted three days when Mr. Connell first saw her. She was then desperately ill. He diagnosed a fibroid with torsion of its pedicle, and advised immediate operation. The uterus and its appendages were rapidly removed, after preliminary enucleation of the large interstitial myoma. The uterine and ovarian vessels were thrombosed, and did not require ligaturing. The patient made a good recovery, though a transient hemiplegia commenced on the day after operation. The cavity of the uterus was distended with blood clot, and the uterus, with its appendages, and the tumour were in a state of infarction. Dr. A. CUFF (Sheffield): Specimen from a case of bilateral malignant *Papillary cysto-adenoma* of the ovaries. There was considerable ascites, and the peritoneum was studded with papillary growths. Three months after operation there were no signs of recurrence. Dr. J. E. GEMMELL (Liverpool), in a

short paper on fibro-myoma uteri as a cause of *Puerperal toxæmia*, related 3 cases which illustrated different methods of puerperal infection dependent upon such growths: (1) Strangulation of the pedicle, leading to sloughing and general septic peritonitis; (2) toxæmia from necrosis of the growth itself; (3) sapraemic infection from the placental side, together with necrosis of the growth. The first 2 cases were successfully treated by subtotal hysterectomy. In the third case a sloughing submucous fibroid was removed piecemeal on the sixth day of the puerperium. Immediate improvement followed, but death, from pulmonary embolism, occurred a few days later. He advocated, in the absence of symptoms of toxæmia, that the tumour should be left until involution is completed, and then dealt with by any operative method which is deemed most suitable; but when toxæmia arises, from any cause whatever, complete or subtotal hysterectomy is the operation of choice, and the safest.

BRITISH BALNEOLOGICAL AND CLIMATOLOGICAL SOCIETY.—At a meeting on March 10th, Dr. SOLLY (President), in the chair, Dr. MANTLE (Harrogate), reopening the discussion on *Intestinal lavage*, Plombières system, said there must be no underrating the diagnostic value of mucus in the stools; mucus normally secreted was invisibly mixed with the faeces. In colitis nervous manifestations were usually striking, but how much as a result and how much as a cause was difficult to say. With the disturbed nervous system there was an unbalanced circulation—hence a condition favourable to congestion of the whole alimentary canal. This explained the frequency of gastric symptoms. There could be no doubt as to the value of intestinal lavage in colitis. Combined with the immersion bath, which reopened the peripheral circulation, the results were brilliant. Mr. LOCKHART MUMFERY said there were many cases of chronic colitis unimproved by lavage or medical treatment. In most of these there was some obstructive or other lesion in the colon which must be removed. A careful examination aided by sigmoidoscopy should be made in all cases of chronic colitis. Appendicectomy gave excellent results in suitable cases, and was much to be preferred to caecostomy, but correct diagnosis was the first essential, and the indiscriminate performance of any single operation was to be deprecated. Dr. FORRESQUE FOX said that serious disorders of the colon were quite exceptional in health resort practice, whilst conditions of constipation with more or less colon irritation were extremely common. The term “muco-membranous colitis” applied to such cases was a misnomer. There was sometimes a deficiency of mucus in the colon (as in the pharynx), and membranes were seldom met with. He had employed lavage in those cases for many years, combined with diet, baths, and exercise. Dr. PARKES WEBER thought that delayed circulation in the bowel, connected with want of exercise and constipation, played a very important part in the commencement of chronic colitis. Treatment in early stages by regular open-air exercise, abdominal massage, and the use of Zander’s mechanotherapy was what was chiefly required. Dr. LEONARD WILLIAMS deprecated the newborn enthusiasm for the Plombières douche at the British health resorts. Colitis was not a new disease, nor was the Plombières douche a new method of treatment. It offered no advantages over an enema properly applied. Mr. PENDLEBURY discussed the surgical points raised by Mr. Mumfery. Dr. PRESTON KING (Bath) pleaded for moderation in the use of Plombières lavage. Dr. HERTZ said that constipation, whether produced by neurasthenia, chronic appendicitis, or weak abdominal muscles, which made defæcation inefficient in visceroprosis, was the chief cause of colitis. Treatment consisted in keeping the bowels empty. Diet, exercises, and drugs generally sufficed; sometimes enemas, and especially the Plombières douche, were required. Appendicectomy was never indicated, as the faecal delay was always in the periphery, so that injections were more effective through the anus than through the appendix. Dr. PAGAN LOWE (Bath) considered that colitis, like appendicitis and neuritis, was a product of influenza, and could usually be treated satisfactorily without intestinal lavage. Dr. REBOUL, of Châtel Guyon, and Dr. BERGOUIGNAN, of Evian, described the treatment as carried out in those resorts. Dr. BUCKLEY, who first introduced the discussion, and Dr. MANTLE both replied.

Rebiletz.

DEEP ANAESTHESIA IN TABES.

PROFESSOR GRASSET, of Montpellier, has published in a small book a series of lectures delivered early in 1908.¹ It is mainly devoted to the consideration of the various forms of deep anaesthesia or deep disturbances of sensation that may occur in tabes dorsalis, and to contrasting them with the better-known superficial disorders of sensation commonly held to be so characteristic of that disease. Deep anaesthesia of the rectum and bladder, and diminution of the sensitiveness of those viscera to distension, have long been recognized in tabes, while Déjerine and others have observed anaesthesia of the vagina and of the os uteri during parturition in tabetic women; but the careful study of such deep anaesthesia was first undertaken methodically by Pitres, of Bordeaux, and has done much to enlarge the semeiology of tabes. Anaesthesia of the testis on pressure is present in about half the cases, and partial anaesthesia in more than half the remainder; an analogous insensitiveness of the breast is often present in tabetic women. Anaesthesia of the epigastrium—the pit of the stomach—on sudden pressure, without loss of the abdominal reflex and without any corresponding cutaneous anaesthesia, has been observed in over 40 per cent. of the cases of tabes examined, and is attributed by Déjerine to pressure-anaesthesia of the solar plexus. Analgesia of the trachea when that organ is pressed backwards in the middle line by a finger, or of the eyeball when it is compressed through the eyelid (deep anaesthesia), or of the cornea and sclerotic to the touch (superficial anaesthesia), or of the tongue to pinching between the finger and thumb, or of superficial nerve trunks to pressure, may all occur in tabetic patients in a percentage as high as 50. Grasset lays particular stress on the analgesia to pressure noted in the tendons of tabetics, first noted by Abadie in 1905. This anaesthesia can be tested in any tendon that can be pinched between the finger and thumb, and is present to a greater or less extent in 80 per cent. of tabetic patients: it is one of the early symptoms of tabes. Analgesia of the bones on percussion, quite apart from superficial anaesthesia of the skin over them, is often found in tabes, and is further brought into evidence by the painless nature of the spontaneous fractures met with in tabetics. Analgesia of the heart is often a striking feature in patients with tabes who are the victims of morbus cordis as well, as frequently happens. The analgesia causes the heart trouble to lie latent until it is accidentally discovered when a physical examination of the patient is made; this is all the more striking, because the lesion common in tabetics is aortic, and aortic disease is so very frequently associated with severe precordial or other pains. Grasset remarks that loss of reflexes and deep anaesthesia of the tendons do not go hand in hand, and discusses at some length the connexion between deep sensations (from the tendons, muscles, etc.), and “muscular sense” and the sense of orientation. He next considers what part of the nervous system it is that controls the deep sensation that is disordered in tabes, and concludes that it is the sympathetic—or rather the vago-sympathetic—nervous system. He does not believe in the division of the whole nervous system into two distinct parts, one the cerebro-spinal, the other the sympathetic, but holds that the sympathetic nervous system is a mixed cerebro-spinal nerve just as much as any other nerve is. He quotes a number of recent writers who have found microscopical changes—atrophy of myelinated fibres leading from the sympathetic ganglia into the posterior nerve-roots of the cord—in the sympathetic system of tabetic patients, and discusses the constitution of the vago-sympathetic chain and its functions.

In conclusion, he repeats that certain cases of tabes dorsalis exist in which many of the classical signs and symptoms of the disease may be absent, while various of the deep anaesthesias mentioned above are present, and make the diagnosis certain. The object of his book is to draw attention to these deep anaesthesias, and it may be warmly recommended to the notice of all neurologists.

¹ *Le Tabes, Maladie de la Sensibilité Profonde. Traçons et Miroirs* de Montpellier. Série Scientifique V. By Professor J. Grasset. Montpellier: Coulet et Fils. 1909. (Med. 8vo, pp. 124.)

ARTERIO-SCLEROSIS.

THE treatise on arterio-sclerosis, by Dr. O. JOSUÉ,² is published at an opportune time, as the subject is one to which considerable attention is being given. The book has a preface by Professor ROGER, who speaks of it and of the work of its author in the highest terms. Dr. JOSUÉ is known as an experimenter who claims to have produced lesions exactly similar to atheroma of the aorta in rabbits by intravenous injections of adrenalin. He did not succeed in obtaining the same results by hypodermic injections or by injecting the solution into the nares, and negative results followed also the intra-peritoneal injections by Erb and intramuscular injections by Kulbs: the latter, however, succeeded with injections into the trachea. The rapidity with which these results were produced is somewhat remarkable. The duration of the author's cases was about five weeks, Erb's twenty days, Kulbs's ten days. Similar results have been obtained by the injection of other substances, such as methyl-aminoketone (Starli), pyrocatechine (Gouget), and, although not mentioned in this book, Adami of Montreal has produced similar lesions by swinging rabbits by their hind legs! Josué answers the objection that spontaneous atheroma is common in rabbits by stating that he only found it once in "a considerable number" of examinations, that Secard did not find it at all in 250, and that Gouget estimates its occurrence as at most 3.7 per cent. He does not accept the ordinary view that the lesion is caused by the hypertension produced by the action of adrenalin on the arterioles. He prefers to believe that it is caused by a specific action on the arterial walls, as J. Teissier and L. Thévenot found that the addition of choline which neutralizes the hypertensive action of adrenalin did not prevent the appearance of the atheromatous lesions. The results of these experiments led him to look to the adrenals as the cause of arterio-sclerosis (which he regards as identical with atheroma), and he claims to have found that the cortex of these bodies is generally hyperplastic in these cases, and although he admits that the medulla rather than the cortex secretes adrenalin he alleges that the cortex also contains a hypertensive substance. It would seem that as he had previously rejected hypertension as a cause of the arterial changes it would have been more to the point to have shown that it contains a substance which has a specific effect upon arterial walls. He relates the results of experiments with many other substances to produce lesions of the aorta, for example, nicotine which gave him negative results, though others have found the opposite, with lead, extract of putrefied meat and red pepper his results were positive, with alcohol negative, with acids, phloridzin, iodide of potassium and sodium, digitaline, ergotine, and several other drugs, microbes and toxins positive, in fact the successful results seem to have been so common as to diminish their value and we hesitate before accepting them as conclusive.

The experimental is after all only a portion of Dr. Josué's book. He gives an excellent and detailed account of the histological changes and of the symptoms associated with arterial disease as well as of the principles of treatment and the remedies now generally in use. The illustrations are good, and by modern methods of staining he is able to demonstrate clearly the presence of fat droplets in the coats of the thickened arterioles. He considers arterio-sclerotic changes to be degenerative, not inflammatory. He enters into an interesting discussion of the relation of arterio-sclerosis to interstitial nephritis, based upon the examination of twenty-three cases, and concludes that there is no strict correspondence between the alterations of the great and medium sized arteries of the kidney and the amount and distribution of the renal disease, but, on the other hand, he finds a close relation between the renal lesion and fatty degeneration of the walls of the arterioles and capillaries of the kidney substance. He describes the changes in the blood vessels in a great many organs, and it appears to us that he to some extent confounds cases in which the changes in the vascular walls are shared with the tissues around and due to a common cause with those in which the arterial change is primary. Of course, it is difficult to distinguish between them, but the author is predisposed to see primary arterial disease

everywhere. This is much the same as the mistake made by Gull and Sutton, who in their illustrations of arterio-capillary fibrosis showed vessels from all sorts of inflammatory patches where the ordinary interpretation would be that the walls of a vessel shared in a change which was common to all the connective tissue in the neighbourhood.

Dr. Josué does not share the distrust of the Riva-Rocci sphygmomanometer entertained by some clinicians, but he proposes the adoption of a somewhat complicated formula instead of taking the simple readings of the height of the systolic pressure.

The book is no mere compilation, and will be read with interest by all who are paying attention to this subject.

SEXUAL PSYCHOLOGY.

*The Sexual Life of Our Time*³ by Dr. Bloch, of Berlin, ran, we are told, into a sixth edition within nine months of its first publication in Germany, so that Dr. ERNEST PAUL had some justification for making a translation into English. Dr. Bloch has spared nothing in approaching his professed aim, which was:

To write a complete encyclopædia of the sexual sciences based upon my own experiences and observations, and embodying the definite opinions I have formed regarding all the important principles involved. I have written this book for all earnest men and women who wish to form well-grounded views regarding the problems of sex and to enlighten themselves concerning the results of the multifarious researches in this province of thought. The immense importance alike to the individual, to the State, and to human society at large of a truly critical knowledge of the relationships of the sexual life is a matter upon which I repeatedly insist in the following volume.

This appeal to all earnest men and women was re-echoed in England by the translator in the following words: "It must be clearly understood that this is a work belonging to the category of 'adult literature.'" With this reservation we may commend the book, which appeals especially to members of the learned professions, medical, legal, and clerical, and next, perhaps, to responsible persons engaged in the instruction of youth, the final appeal of the work being to all those who hold that "the proper study of mankind is man." The sale of the volume being limited, as is customary with such works in this country, to members of the learned professions, it is likely that a much longer period than nine months will elapse before the birth of the sixth English edition. The treatise is a valuable addition to those especial shelves of the library of physiology and frenzy which are already groaning under the weight of Krafft-Ebing, Albert Eulenburg, Magnus Hirschfeld, Havelock Ellis, and other introspective philosophers. The language of the translation is well chosen, the type is excellently clear, and there is a complete and convenient index both of names and subjects.

Professor AUGUST FOREL, formerly Director of the insane asylum at Zurich, is well known to English students of psychology, and especially of psychiatry, by his many works upon these subjects, several of which have been translated into English. His recent volume, *The Sexual Question*,⁴ reflects credit upon the fineness of the adaptor, Dr. C. F. Marshall. It is thin ice, in connexion with which these sexual specialists call a skate a skate, and Dr. Forel himself proclaims serious difficulties for his Anglican adaptor:—

In the domain with which we are concerned (says he) the French public are too much afraid, I think, of crudities and of calling things by their proper name. By veiled words and by indirect locution one may say anything, but I have decided not to employ such subterfuges in treating of such a vital social question with the seriousness that it requires. It seems that there is a fear of young people hearing the sexual question spoken of freely and openly; but it is not taken into account that in hiding these things under half-understood words one only excites their curiosity, and, owing to their being blindfolded, they are delivered into the snares and surprises of debauchery.

² *The Sexual Life of Our Time in its Relations to Modern Civilization* By Ivan Bloch, M.D., Physician for Diseases of the Skin and for Diseases of the Sexual System in Charlottenburg, Berlin, etc. Translated from the Sixth German Edition by Eden Paul, M.D. 1908. London: Rebanan Limited.

³ *The Sexual Question. A Scientific, Psychological, Hygienic, and Sociological Study for the Cultured Classes.* By August Forel, M.D., Ph.D., LL.D., formerly Professor of Psychiatry at, and Director of, the Insane Asylum in Zurich (Switzerland). English adaptation by C. F. Marshall, M.D., F.R.C.S., late Assistant Surgeon to the Hospital for Diseases of the Skin, London. London: Rebanan Limited.

⁴ *Traité de Psychiologie-Sexuelle.* Par le Docteur O. Josué. Préface de M. le Professeur Roger. Paris, J. B. Baillière et Fils, 1909. (Demy 8vo, pp. 416; figures 20. Fr. 10.)

We do not propose to offer a judgement as to whether or no a copious supply of plain-spoken pages upon sexuality is desirable as literature for adults and experts, but we feel inclined to protest against the pose of the author of *The Sexual Question* when he claims to be the instructor of youth. We are reminded of the lines of Horace:

Favete linguis. Carmina non prius audita
Virginibus puerisque canto.

For Dr. Forel in his preface insists upon quoting:

Among several others of the same kind a letter which I have received from a young girl aged 21 years, intelligent, virtuous, educated, and well brought up, but without restraint—

Of whom he says: *Indolence, timidity, and ignorance.*

I begged her to criticize me without pity, for I wished above all things to be clear on the effect produced by my book.

The momentous verdict of this young lady is, by request, anonymous; it is also bizarre, and we need scarcely say, in favour of the appellant, who records his satisfaction in the following phrase: *in my opinion, I have won you.*

I think that the candour, the loyalty, and the maturity of judgement of the sentiments expressed by this young girl are of much more value and are much more healthy than all the prudishness and false shame of our conventional morality.

A work which professes to defy the fear of the French public "of ordurities, and of calling things by their proper names," might almost be regarded as taboo in England—at any rate, for kindergarten use, and we are not yet satisfied that the suggestions of Dr. Forel that youth is to be taught to be surprised at nothing in the way of sexual phenomena are more valuable than the words we have before us of the Master of Trinity College, Cambridge, Dr. Butler, the great Head Master of Harrow School, who wrote: *sexual phenomena are not virtuous nor are they vicious.*

"Precautions should be taken as far as possible to keep vicious or polluting literature out of young boys' ways. I include under this head, and have a reason for each entry, articles in medical or scientific dictionaries. . . . Those who make light of the danger of such books, those who misquote such passages of Scripture as 'To the pure all things are pure,' do not know what they are saying. It is a solemn duty not to put temptation in the way of the young.

Maxima debetur pueris reverentia."

It may be that some of our readers may share the opinion that works of this kind are more fitted for the top shelves of the library of an insane asylum than for the hands of an intelligent, virtuous young girl, aged 21 years.

Les Eunouques a Travers les Ages, by Dr. R. MILLANT, is issued by Vigot Frères, 23, Place de l'École de Médecine, Paris. This postal address in itself suggests that the work should be of scientific interest to the faculty. But, somewhat greedily, the publishers spread their net wide, and hint that the work should have its place in the library of the curious as well as in that of the man of science and the man of letters. It has become the custom of French publishers to supply with each copy of a book sent out for review a printed slip for the use of the reviewer suggesting and, in fact, supplying exactly the notice that the publishers would desire to read. This, too, with the heading *Préface d'insérer*. Now with all respect for a system which tends to promote the enterprise of the publisher and the proverbial indolence of the reviewer, we must protest against this system. An argument which will appeal to the publishers most strongly is that by adopting this method they run a grave risk of forfeiting the sympathy of even the most indolent of critics, who, in a spasm of indignant industry engendered by this suggested slight to his self-respect and independence of thought, is tempted to seek material for censure rather than adopt the laudatory inspiration with its preliminary *Préface d'insérer*. It was in a somewhat carping spirit of resentment at the masquerade of pornography in the guise of science that we perused *Les Eunouques*, which we find to be a reasonably complete treatise on the subject, more interesting, we hope, to the philosopher than to the curious. The author discusses the possible motives which can have induced so many races of mankind in so many ages to submit a proportion of their male population to this mutilation, but the discussion is not illuminating. Dr. Millant gives an interesting account of that strange sect of Russian origin whose head quarters now seem to be in Rumania, the Skoptzys. These people make a virtue of emascu-

lating their males, inspired by a strong religious motive in some obscure way associated with the fundamental principle of their faith, that the Messiah will appear among them as soon as their population has become sufficiently numerous. If the arrival of the Messiah is a consummation devoutly to be wished by the Skoptzys, and if that arrival is to be hastened by increasing the population, we marvel at their craze for castrating their most eligible males—seemingly a check upon population which might cause bones, even those of Malthus, to turn in their grave. The drastic code of the Skoptzys prescribes that the mutilation of males may take place in boyhood; but should any escape this fate and achieve the privileges of matrimony, there must hang over the temporarily happy home the dreaded shadow of the castrator who is to be called in after the second visit of the stork. For upon the birth of a second child a Skoptzy father must be added to the list. By proselytism, sometimes associated with bribery, and also occasionally by violence, the Skoptzy castrators are kept fully occupied over this special work, and it is no uncommon occurrence—so we read—for an earnest Skoptzy to play the part of Shylock to an entire man with a view to exacting the physical penalty for financial default. We are not surprised to read of this strange sect, that they are tighty, well-nourished and shrewd men of business, leading peaceful lives and amassing considerable fortunes, chiefly by horse-dealing and the letting of carriages. In the concluding passages of the book the author sums up the physiological changes following castration, laying especial stress on those observed in the bones, and briefly discusses the hypothesis of an internal testicular secretion. In this chapter lay the chance of the justification of the book as a treatise of service to medical readers; and we regret to find it is totally inadequate. To our mind the most wholesome passage in the book is an echo from Ovid: "La castration aurait dû être le châtiment de celui qui l'inventa."

NERVOUS DISEASES.

Gowers has pointed out that *tabes dorsalis* does not always deserve the epithet of "progressive," formerly applied to this symptom complex, for arrest is frequent and considerable improvement not uncommon. Oppenheim says in the third edition of his textbook that it usually runs a course of ten to twenty years, but may last from twenty-five to thirty, and Marie goes so far as to say that *tabes* does not essentially shorten life. These opinions have led on more than one occasion to the discussion of the question whether this disease may not have undergone a change in character and be now more benign than formerly. As is indicated, however, in a pamphlet by Dr. von MALAISÉ, dealing with the prognosis of *tabes dorsalis*,⁵ it is probable that with the finer diagnosis of to-day, and particularly since the discovery of the Argyll Robertson pupil phenomenon, cases which would at one time have escaped detection are now included in a category which contained formerly only examples of the graver kind. Dr. von Malaisé, who at the time of the preparation of his monograph was assistant in the polyclinic of Professor Oppenheim, of Berlin, was enabled with the help of the Police Intelligence Department of Berlin to trace and examine ninety sufferers from *tabes dorsalis* who had formerly been patients of the polyclinic, and whose first examination dated back at least eight or ten years. Naturally, these patients, coming from the poorer classes, do not give results admitting of general application, for in *tabes dorsalis*, more than most diseases perhaps, the efficacy of treatment, and consequently the prognosis, depends very largely upon a favourable environment. Disregarding, therefore, Dr. von Malaisé's statistics, and only considering a few points of particular significance, we note that, in opposition to Gowers, the author finds that a rapid development of symptoms, and particularly an early appearance (that is, within six years) of symptoms after syphilitic infection, are of unfavourable augury. He agrees with Marie that the greater the variety of symptoms the worse the prognosis; but his results show only a partial agreement with the opinion of Collins that marked sympathetic nerve disorders are of bad omen, for he finds that cases with early and severe gastric

⁵ *Die Prognose der Tabes Dorsalis*. By Dr. E. von Malaisé. Berlin: S. Karger, London: Williams and Norgate, 1906. 32 pp. (5vo. pp. 51. 1s.)

crises often undergo great improvement, thus supporting Benedikt's statement (Ueber Aetiologic, Prognose und Therapie der Tabes, *Wiener Med. Presse*, 1881, Hft. 1, 2, 4, and 5) that prodromal gastric crises and optic atrophy should be classed together from the prognostic standpoint as often marking the commencement of arrest. The author found that in those who showed optic atrophy it occurred in the preatactic stage in 73 per cent., and that in the great majority—that is, in three-quarters—arrest set in with visual failure. On the other hand, late appearing optic atrophy was not in any way related to the progress of the disease. On many points of importance Dr. Malaisé's material was too scanty to be of decisive value, but we may mention, finally, that in the large majority of cases running an unfavourable course the symptoms were first noted in the age period 22 to 36.
